YEARBOOK

OF AGRICULTURE

UNITED STATES DEPARTMENT OF AGRICULTURE

Organization

of the United States Department of Agriculture

CORRECTED TO JULY 1, 1937

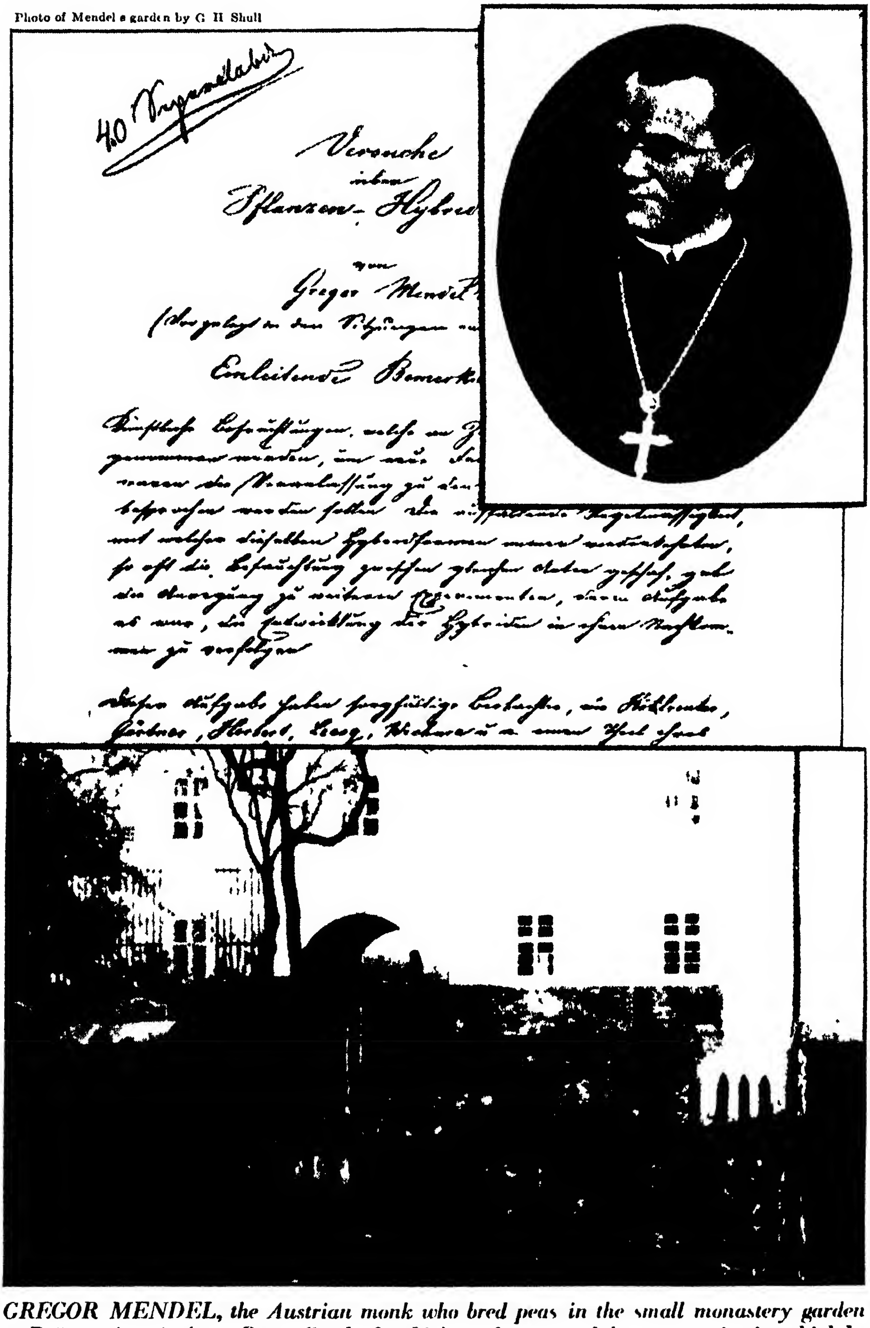
Secretary of Agriculture	*Henry A. Wallace.*
Under Secretary	*M. L. Wilson.*
Assistant Secretary	*Harry L. Brown.*
Director of Extension Work	*C. W. Warburton.*
Director of Finance	*W. A. Jump.*
Director of Information	*M. S. Eisenhower.*
Director of Personnel	*W. W. Stockberger.*
Director of Research	*James T. Jardine.*
Solicitor	*Mastin G. White.*
Agricultural Adjustment Administration	*H. R. Tolley*, Administrator
Bureau of Agricultural Economics	*A. G. Black*, Chief.
Bureau of Agricultural Engineering	*S. H. McCrory*, Chief.
Bureau of Animal Industry	*John R. Mohler*, Chief.
Bureau of Biological Survey	*Ira N. Gabrielson*, Chief.
Bureau of Chemistry and Soils	*Henry G. Knight*, Chief.
Commodity Exchange Administration	*J. W. T. Duvel*, Chief.
Bureau of Dairy Industry	*O. E. Reed*, Chief.
Bureau of Entomology and Plant Quarantine	*Lee A. Strong*, Chief.
Office of Experiment Stations	*James T. Jardine*, Chief.
Food and Drug Administration	*Walter G. Campbell*, Chief.
Forest Service	*Ferdinand A. Silcox*, Chief.[1]
Bureau of Home Economics	*Louise Stanley*, Chief.
Library	*Claribel R. Barnett*, Librarian.
Bureau of Plant Industry	*Frederick D. Richey*, Chief.
Bureau of Public Roads	*Thomas H. MacDonald*, Chief.
Soil Conservation Service	*H. H. Bennett*, Chief.
Weather Bureau	*Willis R. Gregg*, Chief.

For sale by the Superintendent of Documents, Washington, D. C. Price $2.00 (vellum)

Contents

LIMITATIONS *of space made it necessary to omit from this volume some of the ma erial prepared as a result of the survey of plant and animal improvement. Two complete articles were omitted—one on the Improvement of Subtropical Fruits Other than Citrus, by Hamilton P. Traub and T. Ralph Robinson and one on the chromosomal basis of heredity (Studies in the Behavior of Chromosomes) by A. F. Blakeslee, consulting member of the Secretary's Committee on Genetics. Both of these articles, however, will be published in the 1937 Yearbook Separates, obtainable from the Superintendent of Documents, Washington, D. C., at a nominal cost. In order to keep the record complete and unified, the summaries of the articles have been retained in the introductory chapter beginning on page 119. The remaining omitted material consists of the bibliographies on flower breeding and on forest-tree breeding, which include a large number of references, and which will also be published with the text of the articles in the Yearbook Separates; and a few pages of miscellaneous agricultural statistics. The latter are included in substance in the volume entitled Agricultural Statistics, 1937, obtainable from the Superintendent of Documents. A notice of the fact that Agricultural Statistics would hereafter be published as a separate volume appeared in the foreword to the 1936 Yearbook.*

Photo of Mendel's garden by G. H. Shull



GREGOR MENDEL, the Austrian monk who bred peas in the small monastery garden at Brünn, Austria (now Brno, Czechoslovakia), and a page of the manuscript in which he announced, in 1868, the fundamental laws of heredity he had discovered. Mendel's researches attracted no attention until the rediscovery of his work in 1900. Then Mendelism became the foundation for modern plant and animal breeding.

THE YEAR IN AGRICULTURE

REPORT OF THE SECRETARY OF AGRICULTURE TO THE PRESIDENT OF THE UNITED STATES, WASHINGTON, NOVEMBER 10, 1936

PROGRESS OF FARM RECOVERY

FOUR years ago American agriculture was in the depths of depression. Though farm commodity prices had dropped to nearly 50 percent below the pre-war average, the prices of the goods and services that farmers usually buy were at or above the pre-war level. This disparity was a cause of widespread agricultural ruin. Farm bankruptcies were at record heights, dispossessed farmers joined the urban unemployed, and farmers still struggling could not make ends meet. There was a tremendous surplus of farm products; yet consumers were suffering scarcity. Falling farm prices did not help them much, because their incomes were falling too as a result of declining trade and employment. The whole economic system was out of balance.

Since then conditions have changed for the better. The improvement has come about in the manner envisioned in 1933—through agricultural-price recovery with resulting increased demand for city goods. Net farm income this year will be three times that in 1933. All groups of farmers and all agricultural regions have participated in the recovery, though not to the same degree. There is still distress in some regions, as a result of drought in 1934 and again this year. On the whole, however, agriculture is out of the red and making progress toward financial rehabilitation.

This improvement has not been accomplished at the expense of other economic groups. On the contrary, it has promoted their welfare. Consumer buying power has risen with farm incomes, and the average employed wage earner can buy more food today than he could at the peak of urban prosperity in 1929. Food prices are still 15 to 20 percent below the predepression level. In spite of two great droughts in 3 years the total food supply for the current marketing season will be within 1 or 2 percent of what it was in 1935–36. Meat production is below normal requirements; but the output of some other products has increased, and exports are relatively low. Hence the national average per-capita consumption of foods has shown little change. Industrial production is 80 percent above the low point of 1932. In short, the economic system has moved toward balance, with larger incomes in both town and country, and with profits replacing deficits in both farm and city balance sheets.

Farm recovery began in 1933 promptly after the adoption of a national farm-readjustment program, accompanied by revaluation of the dollar. As the farm income rose, farmers started clearing off their debts and taxes. They recommenced buying industrial goods. Recovery went on at a faster pace in 1934, 1935, and 1936, despite the handicap of drought. Between 1932 and the end of 1934 shipments of industrial goods to agricultural areas increased nearly 43 percent, and shipment of goods used in farm production increased 75 percent. New-car registrations in agricultural States in the first half of 1935 were 147 percent larger than in the first half of 1933. Farmers were not monopolizing the benefits of farm recovery but were diffusing it throughout the country and putting life blood into business. What nonfarmers had contributed in processing taxes and benefit payments they got back with interest. Reciprocally the revival of urban trade benefited agriculture, and the whole economic picture brightened.

The Production-Control Programs

In the early stages of the farm recovery, the production of farm commodities had to be restricted so as to reduce the surpluses that were not moving into foreign markets. When drought in 1934 and again this year reduced production too drastically, some people questioned the logic of crop adjustment. Scarcity, however, was never intended and never approached. This country's farm productivity is so tremendous that recovery from drought comes quickly. Full use of the available acreage normally means surpluses. Agriculture produced as usual in the first years of the depression, while urban industry reduced its output by nearly 50 percent.

In bringing their production more nearly in line with demand, farmers were simply copying the behavior of other groups when faced with overproduction and declining markets; with the important difference, however, that only export surpluses came within the farm-reduction program. As soon as the demand improved, farmers increased their acreage and livestock breeding. Though drought in 1934 and 1936 kept the production from rising proportionately, it will rise eventually. Both the farmers and the present National Government aim at adequate production for domestic requirements, plus whatever additional supply can be sold profitably abroad.

Undoubtedly, most Americans want to maintain our agriculture on a proprietary, landowning, family basis. Certainly this Administration does. It is not desirable to have either a peasant agriculture manned by tenants and laborers, or a collective agriculture run by the central Government. This idea involves certain responsibilities. Farmers must be permitted to earn a profit, a margin of income over expenditures; otherwise the family farm becomes bankrupt, and either tenancy or Government farming supervenes.

But if agriculture is to be profitable, it must have prices sufficient on an average and in the long run to exceed its fixed charges and expenses of production; and this is impossible when supplies greatly exceed the effective demand. Those who object to the rational adjustment of the farm output to the farm demand practically take the position that farmers should produce, without regard for the reward obtainable, as long as anyone needs their crops. Needless to

say, production on that basis cannot continue in any business. Profitable farming, in short, means farming adjusted to the available market. If want continues after that has been accomplished, the remedy is to create more buying power, rather than to compel farmers to produce indefinitely at a loss.

Comparison With Industrial Production

Farmers cannot be charged with having promoted scarcity when they readjusted their production for export more nearly in line with the available market. Index numbers of production and prices have been computed in this Department, with the 5 years 1925 to 1929 taken as 100. Farm production was 100 in 1930 and 106 in 1931, from which point it declined moderately to 90 in 1934 and 1935. Industrial production fell year by year after 1929 until it reached a low point of 56 in 1932. Thereafter it recovered gradually until in 1935 the index stood at 82, as compared with the farm production index of 90. It should be borne in mind that the industrial index includes the output of food manufacturers, an item which, of course, reflects farm production. Were this item excluded from the industrial index, the contrast between farm and factory production would be still more striking. Farm production remained high and farm prices relatively low until farm adjustment got under way. Industrial production and prices showed the reverse relationship.

Moreover, the farm situation in 1933 was such that reduced production would have come about eventually in any case, with or without Federal assistance. That is the typical end-product of low prices. Usually, reduced production results from drastic competition and the elimination of the weaker producers. Concerted action after 1933 enabled the vast majority to survive. But this procedure did not reduce production more than it would have been reduced eventually by the other process, and it prevented deterioration of the agricultural plant through farm abandonment.

Looking back over the last 4 years, we can see that despite the droughts we have advanced toward balanced abundance. Four years ago our factories were producing below and our farms above consumer requirements, with both branches of production losing heavily. Today we have a forward movement in both town and country. Farm recovery has reanimated urban life without hurting any group. The disparity between urban and rural production has been substantially removed; likewise the disparity between farm and nonfarm prices. That the results have been beneficial everyone can testify from his own experience. Our higher national income, our increased employment, and the increase that has taken place in the money value of both agricultural and industrial assets show that recovery has been general.

FARM INCOME AND BUYING POWER

This Department makes available two series of farm-income statistics. One series records current receipts from sales plus A. A. A. payments, and the other shows the estimated gross income from the production. Farmers' receipts from sales plus A. A. A. payments in 1936 will probably reach $7,850,000,000, or about 11 percent more than

the corresponding receipts in 1935. This figure is 81 percent more than the cash farm income of 1932 and only 25 percent less than that of 1929. Table 1 shows the decline that took place from 1929 to 1932 and the subsequent steady recovery:

TABLE I.—*Changes in income from 1929 to 1936–37*

Calendar year	Cash income from marketings	Crop year	Gross income[1]
1929	$10,479,000,000	1929-30	$11,941,000,000
1930	8,451,000,000	1930-31	9,454,000,000
1931	5,899,000,000	1931-32	6,968,000,000
1932	4,328,000,000	1932-33	5,337,000,000
1933	5,117,000,000	1933-34	6,406,000,000
1934	6,387,000,000	1934-35	7,276,000,000
1935	7,090,000,000	1935-36	8,508,000,000
1936[2]	7,850,000,000	1936-37	9,200,000,000

[1] Includes cash returns from calendar-year marketings of livestock, and from crop-year marketings of crops plus the farm value of production retained for use in the farm home. A. A. A benefit payments included in gross-income estimates as well as in the annual cash income service.
[2] Preliminary.

It will not be possible to indicate in detail the gross income from the farm production in 1936 until well along in 1937, when the marketings will be more nearly completed. It probably will approach $9,200,000,000, as compared with $8,508,000,000 from the production of 1935. It represents a total advance of about $3,900,000,000 or 72 percent, from the low point of 1932, but it is about $3,000,000,000, or 23 percent, below the figure for 1929. Gross income in that year was 17 percent higher than in 1934–35 and 59 percent higher than in 1932–33. It was 71 percent of the 1929–30 total.

Net income remaining to farmers increased after 1933 proportionately more than the gross income because farm-commodity prices rose more than production expenses and other charges. After paying current production expenses, allowing for the depreciation of buildings and equipment and deducting rent, interest, taxes, and the wages of hired labor, the income available to farm operators for their labor, capital, and management from the production of 1935 was $4,538,000,000. This may be compared with $3,467,000,000 in 1934 and $1,492,000,000 in 1932. Whereas the increase in the gross income from 1934 to 1935 was only 17 percent, the increase in the income available to farm operators was 31 percent. It will be noticed that it was more than three times as large as in 1932. Moreover, much of the expenditures for production items in 1935 went for machinery, buildings, and repairs, which are in the nature of permanent improvements. Farmers' expenditures for capital items in 1935 approximately equaled the estimated depreciation of their buildings and equipment, for the first time since 1930.

EXCHANGE VALUE OF FARM PRODUCTS

Another index of the farm position is the ratio between prices received and prices paid by farmers. Farm commodity prices have risen more since 1933 than the prices of nonfarm goods and services. Previously the trend had been in the opposite direction. In March

1933, with agricultural prices only 55 percent of the pre-war average, nonagricultural prices were still at 100 percent of the pre-war level. Farm products in 1935 averaged 108 percent of pre-war prices, while nonagricultural prices had risen to 125 percent. Farm prices had gained on nonfarm prices, but had not attained pre-war parity. This ratio indicates the exchange value of farm commodities or their unit purchasing power. The index of farm-commodity purchasing power was 55 percent of pre-war in March 1933, 73 percent for the year 1934, and 86 percent for the year 1935. By August 1936 it had climbed to 98 percent.

The purchasing power of farm commodities is not identical with the purchasing power of the farmer. It indicates what a given quantity of farm products will buy, but not what the total volume will command. A closer estimate of the farmer's purchasing power can be derived from the ratio between the cash farm income and the prices that farmers have to pay for goods and services. With prices paid by farmers in 1936 equal to 80 percent of what they paid in 1929, the 1936 cash income of $7,850,000,000 is equivalent to $9,800,000,000 in terms of 1929 nonfarm prices. Otherwise stated, the purchasing power of the cash farm income in 1936 will be only 7 percent less than that of 1929. As compared with the purchasing power of the cash farm income in 1932 it represents an increase of 60 percent. Moreover, agricultural debt charges, taxes, and wage costs were lower in 1936. Allowance made for this additional factor would give an agricultural purchasing power still closer to that of 1929.

Certain aspects of the distribution of the farm income should be noticed. Cash income from meat animals in 1935 exceeded the corresponding figure for 1932 by 73 percent, and in the first 7 months of 1936 it advanced 27 percent over the total for the corresponding period of 1935. From dairy products in 1935 the cash income was 30 percent more than in 1932; the income from poultry and eggs was 45 percent more. These industries made small additional gains in the first 7 months of 1936. From grains the cash income in 1935 was 61 percent more than in 1932 and from cotton 46 percent more. Fruits and vegetables recorded a 41-percent gain. Income from marketings of all crops was 36 percent greater in the first 7 months of 1936 than in the corresponding period of 1935. These percentages do not include the A. A. A. payments.

With marketings and benefit payments included, the total cash income from grains in 1935 was 133 percent larger than in 1932. From cotton it was 77 percent larger. In the first 7 months of 1936 the total cash income from marketings with A. A. A. payments included was 17 percent more than in the corresponding period of 1935 though the A. A. A. payments were considerably smaller.

Regional Percentages Vary

Regional percentages of gain in 1935 over 1932 range from 33 percent in the North Atlantic States to 81 percent in the South Atlantic States. Mainly the regional differences reflect the different price behavior of various commodities, but the aftermath of the 1934 drought was a factor also. Proportionately less gain for the dairy regions than for other regions was a natural consequence of the

fact that the dairy regions had suffered less in the early years of the depression; but for the opposite reason the grain-growing areas show a relatively large increase, though reduced marketings have tended to offset the price gains.

Each of the principal agricultural regions, except the South Central States, showed an increase in income in the first 7 months of 1936, as compared with the corresponding period in 1935. In the South Central States, where smaller Government payments offset an increased return from marketings, the income was approximately the same. The gains in the other regions ranged from 14 percent in the North Atlantic, South Atlantic, and Western States to 23 percent in the West North Central States.

Accurately to measure the respective influences of the factors responsible for the recovery in farm incomes is difficult if not impossible. Mainly the improvement reflects price gains, supported by increased consumer buying power. Factors in the price gain include the revaluation of the dollar, the A. A. A. adjustment programs, the reduced production caused by the 1934 drought, and the liquidation of surpluses. In 1936 increased marketings were a factor in the income gain. Farm prices in the first 7 months of the year averaged slightly lower than in the corresponding months of 1935. In the later months, however, farm prices advanced as a result of the drought, and for the full year the farm-price average will probably exceed that of 1935.

In estimating the prospects for the longer future the most basic factor is the level of consumer incomes. Broadly, the income of agriculture varies more closely with the national income than with the level of farm prices. It is encouraging to note that the money income of the nonfarm population in August 1936 averaged 13 percent more than in August 1935 and 32 percent more than in the corresponding period of 1933. With their improved income, consumers were able to buy 7 percent more food and 12 percent more of the other items in their budget than in the previous year, but 6 and 11 percent, respectively, less of these items than in 1929. Earnings per employed worker have more than kept pace with food prices. Needless to say, farmers as a result of their income gains can deal more effectively with the consequences of the 1936 drought than they could with those of the drought of 1934.

Farm Prices and the Consumer

Effects of the drought on the cost of living will probably be similar to those produced by the drought of 1934. From crop data available in September it was estimated that for the 1936–37 season food supplies in general will be about 3 percent below the 1935–36 level, about 1 percent below the level of 1934–35, and about 5 percent below the 1925–29 average. Certain vegetables, particularly potatoes, will be in short supply. The output of fruits and vegetables and of dairy products will be lower, and after the turn of the year the supply of meats will be reduced. This will result in higher meat prices to some extent offset by seasonal declines in other food prices. In the comparable situation after the 1934 drought, retail food prices as a whole in the first half of 1935 averaged about 11 percent higher than they

did during the first half of 1934. Food constitutes only about one-third of total living costs, hence an increase of, say, 10 percent in the cost of food tends to produce a rise in total living costs of only about 3 percent.

Analysis of the trend in nonfarm income indicates that consumers' incomes in the first half of 1937 will increase at least as much as the cost of living. In other words, the purchasing power of consumers generally, in terms of goods and services, will not decline. Had there been no drought, it would have increased; and the foregoing remarks do not signify that consumers can regard with indifference the great change produced by the drought in the supply situation. But the main effect will be temporarily to arrest a gain rather than to cause a drop in the real income of consumers. Wage earners actually employed could buy with their wages more of the necessities of life in the summer of 1936 than they could in 1929 because retail prices were lower on the average. In terms of foods the purchasing power of employed workers actually advanced after 1929, when farm prices began falling. It remained above the 1929 level and reached a new high point in 1936.

In total purchasing power the position of city workers deteriorated during the first years of the depression. Pay rolls declined, while many nonfood items in the family budget remained unchanged. In 1934, 1935, and 1936, however, nonfarm labor incomes increased. These incomes for the first half of 1936 aggregated $23,492,000,000, as compared with $19,617,000,000 in the first half of 1933. More men were engaged in manufacturing in the summer of 1936 than at any previous time in the last 5 years; in July industrial production was 108 percent of the 1923–25 average, the highest point reached since November 1929. According to the seasonally adjusted index of the Federal Reserve Board, the July industrial production was 83 percent above the low point to which it fell in March 1933. The relatively small rise in the cost of living which will be the inevitable consequence of the drought will be substantially offset by recovery in urban buying power.

OUR NATIONAL AGRICULTURAL POLICY

It is commonly believed that the United States never had a truly national agricultural policy until after the World War; but the country has always had a national agricultural policy. In the period of westward migration, of rapid land settlement, and of ruthless exploitation of natural resources, the policy was negative. It was mainly one of noninterference with the private appropriation of land for use or misuse. Despite its laissez-faire character, we cannot call that procedure a mere lack of policy. It expressed a definite philosophy and, indeed, a definite program. It was what the dominant forces in the country wanted and what the majority of the people at least tacitly accepted. Our national agricultural policy in the nineteenth century reflected the belief that national welfare could best be promoted through individualism and unrestricted competition.

For a long time this theory apparently stood the test of practice. With abundant land, an open frontier, and a relatively sparse population, the quickest way to increase production, and therefore wealth,

was to get the resources into private hands. Occasionally production overshot the market; but the resulting depression did not last long and did not shake the country's faith in the exploitation program. Various administrations encouraged farming, ranching, lumbering, and other land uses through homestead laws, grazing privileges, land grants, favors to transportation companies, lenient taxation, and irrigation. Few looked forward to the closing of the frontier and to the ruthless competition that would ensue. Most people seemed to think the policy that had been adopted could be continued indefinitely.

As a matter of fact, as most people now perceive, the exploitation policy created problems that today necessitate a conservation policy. Recklessness in one age inevitably imposes prudence on the next. There are sharp contrasts between the agricultural views and programs that dominated the nineteenth century and those that shape our agricultural policy today. But the contrast does not mean that the present has broken with the past or that tradition has been sharply wrenched from its natural path. On the contrary, it signifies that cause and effect have operated normally. The new agricultural policy is the direct result of the old one and of the conditions and problems which the old policy created. As the occupation of the continent proceeded, the expansion program ran out of material. It ran out of land and forced the land hungry into submarginal farming, destructive grazing practices, and forest devastation. Land charges accumulated on the older-settled land and drove producers into overproduction. Exploitation, in short, created the need for conservation, and simultaneously excessive competition generated a need for corrective regulation. It is because our forbears went too far in one direction that we must now move in another.

No Break With Evolutionary Trend

In the transition from the old to the new agricultural philosophy there is no sudden break with the evolutionary trend, and no capricious improvisation of new doctrine. On the contrary, the link between the old exploitation and the new conservation, and between the old unregulated competition and the new principle of cooperative adjustment, is direct and close. Perhaps the authors of the exploitation program, were they here today, would disown their offspring; but the parentage can be demonstrated. After the spendthrift has wasted his money he must begin to save; after a country has squandered its natural resources it must learn to husband what remains. Our national agricultural policy since the World War has been criticized as confused and uncoordinated, but study of it will reveal a logical and indeed predestined course.

Thus the Federal Farm Board came into existence to handle surpluses left by wartime and post-war expansion. The McNary-Haugen plan, though twice vetoed, stamped its mark on subsequent legislation as a first approach to the problem of the export surplus. The A. A. A. programs were an emergency effort to substitute concerted for haphazard crop adjustments in a catastrophically falling market and to bring agriculture abreast of urban industry in the regulation of production. The new Soil Conservation and Domestic Allotment Act, though weaker in crop-adjustment power than the measure it replaced,

had the great merit of launching a positive attack on the dual problem of soil destruction and unbalanced cropping. In varying degrees all these approaches to the agricultural problem betokened a national recognition of the fact that modern problems cannot be solved by ancient formulas, and that agricultural policy today is necessarily in large measure the opposite of what it was in the period of the open frontier.

Agricultural policy draws its inspiration, not from the accidents of politics but from fundamental economic changes. In the shaping of American agricultural policy we can distinguish two great controlling forces, each of recent origin. First, of course, is the disappearance of the open frontier and the resulting pressure of population on the resources available with its threat of soil wastage and soil destruction. Second is the world-wide growth of economic regulation, not only in trade but in production. Governments are assuming greater and greater responsibilities for the regulation of commerce both domestic and foreign, and industry is becoming cartelized throughout the world. Into an economic system of that kind, a purely competitive, wholly unregulated agriculture will no longer fit. These two great forces seem destined to exert an increasing influence which will express itself in legislation and policy no matter what political party may be in power. Modern agricultural policy in the United States is not the arbitrary invention of an economic group with a special interest to promote but is a national response to an altered economic world. It is not merely an attempt to deal with temporary evils but a profound readjustment to permanently changed conditions.

Landmarks in Agricultural Policy

It is interesting to recall the contribution of the past to present agricultural policy. In 1862 Congress passed the Morrell Act, providing Federal grants of land to the States for the establishment of colleges in agriculture and the mechanic arts. After half a century of progress in agricultural technology, agriculture began to demand economic guidance. Accordingly, this Department developed extensive and varied economic services in which research was combined with the regular gathering of crop and market data, and with numerous related services such as commodity grading and standardization, and shipping- and receiving-point inspection. In 1921 these and other activities were concentrated in the Bureau of Agricultural Economics. In 1922 Congress passed the Capper-Volstead Act, giving legal recognition to the right of farmers to organize cooperative associations for the marketing of their products. In 1927 and again in 1928 Congress passed the McNary-Haugen legislation, though each time the legislation encountered a Presidential veto. Then came the Agricultural Marketing Act of 1929 and the creation of the Federal Farm Board. In 1933 the Agricultural Adjustment Act, with its provisions for processing taxes and cooperative crop adjustments, went into effect and remained in effect until the United States Supreme Court invalidated it in January last, through decisions in the Hoosac Mills and rice millers' cases. Throughout the entire period covered by this brief review American farmers manifested an in-

creasing tendency to effect organization and also to look to the Federal Government for aid in solving their economic problems.

Because of the adjustments made under the Agricultural Adjustment Act during the last 3 years and because the drought helped to liquidate certain of the surpluses, the present program under the Soil Conservation and Domestic Allotment Act is well fitted to present needs. Farmers recognize that, while this agricultural conservation program will be of immediate help in stabilizing supplies through the encouragement of more extensive uses of land, the program itself is not a direct production-control measure. A return to normal weather conditions would revive the problem of agricultural surpluses. I am inclined to believe that farmers understand what confronts them in the future and that they will look forward to making use of the method of meeting the problem of surpluses which the Supreme Court left open to them. The Soil Conservation and Domestic Allotment Act contains a provision which will facilitate this step in 1938 should farmers decide to meet their supply problem through cooperation of the States. This provision is, of course, the direct descendant of the invalidated Agricultural Adjustment Act, and preserves some of the ideas contained in that measure, as well as some of the principles developed in the application of the A. A. A. programs. It would be well, therefore, before examining methods and results under the new law, to glance back at the legacy bequeathed by the A. A. A.

Agricultural Adjustment Act Effective

It is evident, from the improvement that took place in the position of agriculture between 1932 and 1935, that the Agricultural Adjustment Act forwarded its main purpose. This was to eliminate the crushing surpluses that had piled up previously and to raise farm incomes immediately through various measures calculated to support prices. From 1932 to 1935, the period during which A. A. A. programs were in effect for cotton, wheat, tobacco, corn, and hogs, the combined farm cash income from these commodities increased 90 percent. Cash income from these five major commodities increased from $1,365,000,000 in 1932 to $2,593,000,000 in 1935. From all other farm products the cash income increased from $3,012,000,000 in 1932 to $4,307,000,000 in 1935. In 1932 the largest farm population in the Nation's history had the smallest farm cash income reported in the 26 years for which records are available. The turning point came with the adoption of the Agricultural Adjustment Act, though this measure was only one of the factors responsible for the agricultural improvement. Dollar revaluation, business recovery, credit relief extended through the Federal Farm Credit Administration, and other influences contributed. All these influences combined gave farmers in 1935 a cash income available for living larger than in any year since 1929. They had to pay somewhat more for goods and services in 1935 than they did in 1932, but with allowance made for that, the purchasing power of the farm cash income in 1935 was still 35 percent larger than it had been in 1932.

The great drought of 1934, which cut our production of feedstuffs in half, necessitated modifications in the A. A. A. program so as to

encourage production of emergency feed crops that year and to provide for certain increases in production the next. It became advisable also to work toward a better coordination of the various commodity programs and to provide for greater regional and area differences so as to promote good farm management and good land use. Certain shortcomings had developed in the emergency application of the programs, notably a tendency to fix or freeze production in the historic mold, without proper regard for the changing requirements of different areas. But the crop-adjustment programs had shown themselves to be useful in promoting soil conservation and good farming. They fostered some shift from soil-depleting cash crops, such as cotton and wheat and corn, to soil-building crops such as grasses and legumes.

To strengthen and develop this favorable tendency, the A. A. A., working with the State experiment stations and with other branches of this Department, launched studies in regional planning and modified its crop-adjustment contracts with farmers. It began to place less emphasis on flat percentage changes in production and more on differential adjustments to the requirements of local as well as of national conditions. In this way the A. A. A. developed principles which found continued application when the invalidation of processing tax and production control provisions of the Agricultural Adjustment Act led Congress to pass the Soil Conservation and Domestic Allotment Act. Under the A. A. A. the primary objective was production control, with soil conservation a secondary though increasingly important object. Under the new law soil conservation becomes the primary aim, with some crop adjustments coming as a byproduct. Probably in a period of good crops and high yields the degree of crop control attainable under the new measure will not be adequate, but for the time being it works for a better crop balance. The emphasis it puts on grass and legumes has the double advantage of making our agricultural system less intensive, while at the same time conserving soil wealth.

Methods Under New Law

Under the Soil Conservation and Domestic Allotment Act the Federal Government in 1936 made grants to farmers cooperating in soil-conserving and soil-building programs. It did not make use of contracts. Cooperating farmers simply planned their operations in line with definite soil-conservation standards, worked out with producers, soil specialists, and State agricultural leaders. They obtained their grants after officials had checked the performance with the standards. For this purpose Congress made $470,000,000 available for the year, the goal for which was to have 130,000,000 acres in soil-conserving crops as compared with 100,000,000 acres in 1930. Though the program for the year was national in scope, the country was divided for administrative purposes into five regions—the northeastern, the east central, the southern, the western, and the north central—and the practices for which payments were made and conditions which had to be met were varied so as to meet the particular needs of the farmers in each region.

After January 1, 1938, the program will enter upon a State-aid phase; in other words, the Federal Government thereafter will make soil-conservation grants, not directly to individual farmers, but to the States for distribution to cooperating farmers. The Soil Conservation and Domestic Allotment Act sets up five objectives: Preservation of soil fertility, diminution of soil exploitation, promotion of the economic use of land, the protection of rivers and harbors against the results of soil erosion, and the attainment of parity income for agriculture. Power to promote the last-named object will not be available until the State-aid phase of the act goes into effect, but economists and farm-management specialists are already studying the means by which it may be used, provided it is needed.

Soil conservation and good farm management were important objectives under the A. A. A. programs. As experience showed the need, the A. A. A. modified its original requirements so as to give contracting farmers more scope in combining their various crop enterprises in harmony with the national crop-adjustment programs and more incentive to protect and restore soil values. In the north-central region, for example, from two-thirds to three-fourths of the acreage diverted from corn, wheat, cotton, and tobacco went into legumes and grasses. This diversion, though of a temporary nature, was a good beginning in cooperative soil conservation. It was the first large-scale effort to correct the bad effects of cropping practices developed in the wartime and post-war booms, when much land not suited to continuous intensive cultivation was brought under the plow. In the South, farmers were allowed to increase their acreage and production of food and feed crops, which meant an increase in the farm standard of living.

The necessity for soil-conserving practices was long overdue. Soil depletion had characterized American agriculture for decades, and the overcropping which took place during and after the World War made matters worse. Though the demand for farm products declined in the twenties, and though farmers had apparently a strong motive to alter their cropping systems, the acreage of cultivated, soil-depleting crops continued to increase. Burdened with debt and driven by low prices to seek compensation through more and more production, farmers kept on mining the soil. The A. A. A. enabled them to adopt a better course. With higher prices and benefit payments in view, they could begin to think of their permanent, as well as of their immediate, interest in the land and, to some extent, could stop selling the fertility of the soil piecemeal with the crops at low prices to foreign countries.

Research and Demonstration Authorized

The soil problem received special recognition when Congress passed the Soil Conservation Act of 1935, which provided for a general program of research and demonstration to be conducted by the Soil Conservation Service in cooperation with the State experiment stations and with farmers. Broadened and amended after the Hoosac Mills decision, the measure evolved into the Soil Conservation and Domestic Allotment Act. This act recognizes a social as well as an individual interest in soil conservation and provides the individual

farmer with means to advance both interests simultaneously. It facilitates a concerted effort to correct the grave mistakes that have been made in the past, and particularly since the World War, in the use of farm land.

Much of the land that came under the plow for the first time during and after the World War lies in the western Great Plains, and cannot be expected in normal circumstances to give profitable yields. Moreover, it is extremely subject to wind erosion. In the older cultivated regions, especially in the Corn Belt and South, there is heavy overcropping. In the Corn Belt, according to a report of the National Resources Board, overcropping is a major soils problem, particularly on the erosible land along the eastern edge of the sand hills, the plains of southern Nebraska, and the hilly areas of southern Iowa, northern Missouri, and western Illinois. Overcropping in this area is damaging more than 36,000,000 acres of farm land. Besides exposing the land to erosion, it is making soil harder to work, reducing the plant-food content and exposing land to increased danger of drought. Erosion and the drastic depletion of soil fertility due to overcropping are common throughout the South, and erosion is far from unknown in New England, even though much of the farm land is already in soil-conserving crops.

What is happening to farm lands throughout wide areas may be indicated by the results of experiments on the historic Morrow plots at the University of Illinois. One comparatively level plot which had been continuously in corn and oats for 23 years lost 4 tons of humus per acre, and yields steadily declined. On another plot, on which corn, oats, and clover were rotated, and on which fertilizers were applied, the soil retained 14 tons more of organic matter per acre than did the soil of the corn-and-oats plot. Studies in Ohio revealed that during the last 60 years the adoption of better varieties, better seed, and scientific methods for the control of insects and plant pests merely balanced the downward trend in the average productivity of the soil. In other words, more than half a century of applied science showed no net gain because it did not include effective soil conservation. Comparable studies in Iowa demonstrated that present farm practices will not maintain the fertility of the soil and control erosion, and that in order to do so it will be necessary to reduce the corn acreage considerably. On rolling land the major problem is soil washing. Land cropped continuously in corn, in soil tests at the University of Missouri, lost seven times as much soil as land planted to a rotation of corn, wheat, and clover, though the slope was only 4 percent. Land kept in bluegrass lost only one-sixtieth as much soil as that kept in continuous corn.

Soil Depletion in the South

Because of the system of farming followed in the South, the soil has been greatly depleted. Southern farmers devote a larger percentage of their cropland to soil-depleting crops than do farmers in any other part of the country. In the nine States of the southern region, with the exception of Florida, the ratio of soil-depleting cropland to the total cropland ranges from 76 to 92 percent and averages approximately 80 percent. The large percentage of clean-

tilled row crops is a heavy drain on soil resources. In acreage cotton and corn are the principal crops, though there is a considerable acreage of wheat in Oklahoma and Texas. Cotton and corn both leave the land comparatively bare in the winter and subject to soil erosion. The mild climate and the heavy rainfall aggravate the problem.

In 1936 the nine States shifted about 13 million acres from soil-depleting commercial crops to soil-conserving noncommercial crops. This was more than 40 percent of the total acreage so diverted in the United States. Soil conservation in the South calls for a relatively large percentage of diversion. But the dense farm population and, in recent years, the low price of cotton have made the operation difficult. Eleven million people, or one-third of our farm population, live in the nine States included in the southern region.

Prior to 1936 this situation was alleviated to some extent by the agricultural adjustment programs, which embodied a number of soil-conserving features; and in 1934 and 1935 about 14 million acres normally in cotton was shifted to the production of food and feed crops, and to crops that conserve the soil. The acreage of soil-conserving crops in the South in 1936 was the largest on record.

In setting up the soil-conservation program in the western region it was necessary to take into consideration a great diversity of crops, of types of farming, and of farming practices. This region comprises Arizona, California, Colorado, Idaho, Kansas, Montana, New Mexico, Nevada, North Dakota, Oregon, Utah, Washington, and Wyoming. In the more humid areas the major problem is that of preventing erosion by water, while in the Great Plains erosion by wind demands attention. The so-called dry-land area requires special safeguards. Irrigation farming has its peculiar problems. In parts of Oregon, Washington, and northern Idaho summer fallowing enters into the system of farming and calls for appropriate conservation practices. In certain areas payments were made for contour cultivation, and particularly for contour listing, which tends to check erosion by both wind and water. Where wind erosion is serious, strip cropping and strip fallowing were encouraged. In three States payments were made for the use of lime or gypsum in soil building; and in States where noxious weeds are very prevalent, weed-control measures were regarded as a soil-building practice.

Organization for the Program

The organization set-up for carrying out this year's program retained the principle of farmer cooperation, which had been developed under the A. A. A. programs in 1934 and 1935. As a coordinating body between the Federal Administration and local bodies there was established for each State a State agricultural conservation committee. This consisted of from three to five members, appointed from more or less distinct type-of-farming areas. The State committees generally exercised advisory and supervisory functions. They assumed the responsibility for checking the work of the county committees in establishing bases for supervising the checking of performance by cooperating farmers and for reviewing county expenditures

and program disbursements. They were also responsible for the relative cost, operation, and the effectiveness of the programs.

Within the counties the organization was similar to that established under the earlier A. A. A. programs. Each county had its county and community committeemen, all of them farmers. These committeemen were elected by their neighbors in each township or other similarly defined area, to assist program participants in executing work sheets and in planning their farming operations in line with conservation standards. Also, the township committeemen helped, at the end of the season, to check performance and to certify the claims of cooperating farmers for Federal grants. Responsibility for supervising and coordinating the work of the various community committeemen, for reviewing program forms and documents, and for making final recommendations for the adjustment of individual "soil-depleting bases" within the prescribed limits for the county, rested with the county committee, which accordingly had authority to investigate local problems. Educational work necessary in the explanation and application of the programs was under the direction of the State agricultural extension services, which also were given large administrative duties in the West and South.

In determining an individual farmer's contribution to the national soil-conservation goal and therefore establishing the amount of his claim upon the grant funds available the starting point was the soil-depleting base. Cropland uses were divided into two major classifications, soil-depleting and soil-conserving. Among the soil-depleting crops may be mentioned corn; small grains harvested for grain or hay, or seeded alone and pastured; annual grasses pastured or harvested for grain or hay; soybeans, cowpeas, and field beans if harvested for grain; the sorghums, potatoes, commercial truck and vegetable crops, sugar beets, tobacco, and cotton. In the soil-conserving category were included most of the legumes and perennial grasses; soybeans, field beans, cowpeas or field peas, if these crops were turned under as green manure; small-grain crops if turned under as green manure and followed by soil-conserving crops; orchards and vineyards interplanted with winter cover crops; acreages summer-fallowed if followed with soil-conserving crops. The two categories include many crops not here mentioned. Those cited merely illustrate the principle. After drought conditions developed in June and July, the Administration authorized many changes and additions to the crop classifications so as to meet the unexpected weather conditions.

For the farm owner or operator who planned to cooperate, the county committees established a general soil-depleting base, and in the South special bases were established for cotton, tobacco, and peanuts. This base represented a normal acreage of the soil-depleting crops on the farm, with the total acreage serving as the starting point. The county limit was the ratio of the soil-depleting crop acreage to all farm land or to all cropland in the county. As representing the most normal period for the production of soil-depleting crops in recent years, the north-central region took 1932 and 1933 as the base years for establishing the county limits, the western and southern regions took 1928–32, and other regions adopted different base years. County

committees notified farmers of their preliminary bases, but these were not necessarily final. Farmers had the right to appeal for reconsideration of their bases, first to the county committee and then to the State committee. This appeal procedure, besides being consistent with the democratic principle underlying the whole program, permitted the correction of unintentional errors. By taking all possible precautions to have the bases fairly established, the Administration hoped that they would prove satisfactory not only for the current year but for subsequent programs.

Two Classes of Payments

Farmers cooperating in the soil-conservation program could qualify in 1936 for either or both of two classes of payments, the class 1 or soil-conserving payment, and the class 2 or soil-building payments. The class 1 payment was available to farmers who diverted a portion of their soil-depleting base acreage to soil-conserving crops or uses. Farmers were eligible to receive this payment on any number of acres up to 15 percent of their general soil-depleting bases, up to 35 percent of their cotton bases, 30 percent of their tobacco bases, and 20 percent of their peanut bases. It was determined on a per-acre basis and averaged approximately $10 an acre for the entire country, varying quite widely, of course, with variations in the productivity of different counties and of different farms. Farmers desiring to qualify for the class 2 or soil-building payment had to adopt certain approved practices calculated to restore soil fertility.

These practices varied in different parts of the country but generally included new seedings of legumes and perennial grasses, seeding of soybeans, cowpeas, etc., for green manure, and applications of limestone. In certain dry areas farmers could qualify for small per-acre payments if they planted rye as a nurse crop for pasture grasses or if they strip-fallowed in such a way as to check wind erosion. In some areas payments were made for terracing. There was a top limit on the total amount of class 2 payments that a cooperating farmer might receive, which was generally the same number of dollars as there were acres of soil-conserving crops on cropland on his farm in 1936. Hence the larger the acreage of soil-conserving crops on the farm in 1936 the larger the soil-building allowance. A farmer could earn all or part of the allowance, in proportion to the extent to which he applied the recommended practices.

The farmer's response to the agricultural-conservation program has been gratifying. Although the entire program had to be developed after the signing of the Soil Conservation and Domestic Allotment Act on February 29, more farmers applied for work sheets or asked for bases to be established than cooperated in the several commodity programs under the A. A. A. In general the cooperation was about the same as under the A. A. A. in those areas where corn, cotton, wheat, and tobacco were the major crops, and much greater in those areas where general and mixed farming is found, as, for example, in dairy regions like Wisconsin and New England and the mixed-farming sections in California. This, of course, was due to the fact that the new program was much more flexible than the old com-

modity programs, that it was better regionalized, and that each farm was considered as a unit.

As already indicated, the primary aim of the new program is the conservation and improvement of the soil, with crop control an incidental byproduct. With the move next year from a Federal to a State-aid basis, crop adjustment may become more important. When the States disburse the soil-conservation grants, soil conservation and crop adjustment may be combined legally. In fact, the two principles go naturally together. There was a steady growth of soil conservation under the original A. A. A. programs, and there should be a similarly steady growth of crop control when the national program for soil conservation gets well advanced. For it is obvious that the shift from soil-depleting to soil-conserving crops answers not only the needs of the soil but also the needs of the permanent agricultural market.

The shift from soil-depleting crops, such as cotton, tobacco, and wheat, to soil-conserving crops, including primarily hay and forage, may go along with an increase in the animal enterprises commonly using the latter crops, particularly the beef and dairy enterprises. This tendency the present drought partially obscures. An increase in the relative output of these two enterprises, particularly dairying, appears desirable from the national point of view. But it should be recognized that farmers in the major dairy areas have long followed farm practices and cropping systems of a soil-conserving and soil-building character. Care must be taken not to work a disadvantage upon them. This problem has been attacked by continued efforts to secure orderly and stabilized fluid-milk markets through marketing agreements and orders, through the purchase of price-depressing temporary surpluses and their distribution through relief channels, and through the elimination of cattle infected with Bang's disease and tuberculosis. In addition payment for practices of a soil-improving character enables these farmers to improve their pastures and hay lands.

Long-Time Effects on Production

The present phase of drought-caused shortage can only be temporary. Under normal weather conditions our agricultural industry can oversupply its market, and the natural reaction from the present drought will be for it to do so. For the moment it may seem premature to talk again about overproduction, but experience proves that under blind competition one or two good crop years can pile up surpluses.

It will be well to remember, when overproduction impends, that soil conservation alone is not a sufficient preventive. Soil-conservation practices tend to have more effect on output at first than they do later. In their early stages they reduce the average intensity of cultivation significantly, and therefore the tendency to oversupply the market. Eventually, however, they increase soil productivity; it is obvious, moreover, that less intensive cultivation of part of the farm area may promote more intensive cultivation of the remainder, particularly if the farm population is excessive. Unless the foreign as well as the domestic demand for American agricultural products revives, the rehabilitation of the soil through soil-conservation programs will combine with other factors in the agricultural situation

to confront the country again in the near future with the absolute necessity of establishing a good adjustment between production and market requirements. Permanent agricultural policy should achieve soil conservation, consumer protection, and crop control together.

The transition from emergency crop adjustments to a more permanent program, with good land use and higher current incomes ranking equally as objectives, began in 1935, nearly a year before the Supreme Court decided the Hoosac Mills case. It started with a regional-research project undertaken by this Department in cooperation with the land-grant colleges and the State experiment stations.

Farm-management specialists had recognized that a shift toward less-intensive cropping, accompanied by soil conservation and soil building would reduce surpluses and at the same time lower the costs of production. They did not know, however, exactly what adjustments were necessary in cropping systems. Neither did they know what the effect of specific regional changes would be on total production. The research project sought light on these questions.

At the same time that it sought the advice of the experiment stations, the Department asked farmers for their recommendations. It did so through a county-planning project, which was in full swing by the fall of 1936. Committees of farmers were formed in 2,500 agricultural counties throughout the United States. These committees offered opinions on the same questions that were asked of the experiment-station specialists. They estimated the county adjustments apparently necessary in crop and livestock systems to maintain soil fertility, control erosion, and promote more efficient farm management.

Specialists in the Department and in the State experiment stations are summarizing the results. The estimates of the farmers are being combined by type-of-farming areas, so that they may be compared directly with the estimates of the experiment station specialists. It will then be possible to arrive at final estimates which will command the agreement of both the farmers and the experiment station group. This year the farmers' committees studied the apparent results of the soil-conservation program, and offered suggestions for its improvement.

This work with the farmers and the technical specialists reflects the Department's recognition of the importance of drawing on the knowledge and experience of local groups in formulating national agricultural programs. Reliance on local interest and cooperation is more necessary now than ever, because the shift from crop control to soil conservation enhances the importance of local knowledge and local action. There was considerable decentralization of administrative responsibility under the original A. A. A. programs. There must be considerably more in planning agriculture on the new basis. In no other way can the procedure be at once efficient and democratic.

METHODS OF EROSION CONTROL

This year's exceptional weather drew attention forcibly to the need for a regional and local, as well as a national, approach to the problem of the soil. Floods in the Northeast and elsewhere and dust

storms in the Great Plains demonstrated that in some areas all the land should be brought under uniform programs for the control of erosion. Operations launched under the Soil Conservation and Domestic Allotment Act moved in the desired direction, but the national approach cannot do everything that is necessary.

There is need also for intensive local operations in which each farm may be treated as part of a regional pattern. As is well known, good soil care on one farm may be counteracted by neglectful methods on neighboring farms. Efficient soil conservation cannot be promoted merely by the action of individual farmers; it requires coordinated effort through entire land-use regions.

Research, demonstration, and operations in this field are the special tasks of the Soil Conservation Service, which was established in 1933 in the Department of the Interior and transferred 2 years later to the Department of Agriculture. This Bureau cooperates in research with other Federal agencies as well as with the State agricultural experiment stations. It cooperates also with the Extension Service in the development of demonstration projects and in educational matters relating to erosion control. Essentially the methods of the Soil Conservation Service are intensive. It makes detailed surveys and studies the erosion conditions of entire land-use regions as a basis for specific recommendations and preventive practices.

The studies include topographical and contour mapping, erosion surveys, soil analyses, observations of land-use practices, and the testing of different expedients and practices. The demonstration projects accomplish three distinct purposes: They test various methods of erosion control, provide demonstrations of the appropriate methods, and actually prevent erosion on the particular lands involved. All available methods, such as correct cropping and rotations, tillage and engineering practices, moisture conservation, and pasture and forest development are applied in combination.

Mistaken land-use practices in the United States have caused the ruin by erosion of some 50,000,000 acres and seriously damaged 50,000,000 acres more. Much additional land is in danger. Soil erosion injures not merely the owners or the occupants of the eroded lands and their immediate neighbors; its harmful consequences extend through whole watersheds and throughout the country. Erosion dissipates fertile soil in dust storms, piles up soil on lower slopes, covers rich bottom land with poor subsoil, destroys food and cover for wildlife, and increases flood hazards. Furthermore, it causes the silting and sedimentation of stream channels, reservoirs, dams, ditches, and harbors, and damages roads, railways, irrigation works, power plants, and public water supplies. It is a public as well as a private liability, and it can be dealt with effectively only by cooperative endeavor.

Soil Losses Heavy in 1936

Soil losses from the floods last spring were tremendous in the Northeast and in Texas and Colorado. Soil blowing in the Great Plains, with reduction of the vegetative cover, emphasized the need for a radical change in the farm system in certain areas, as well as for compre-

hensive soil-conserving programs. These conditions brought home to farmers generally, and to other interested groups, the fact that the soil problem has distinct regional and local peculiarities, the treatment of which requires methods appropriate to each region and each locality. Visible damage left by the floods and dust storms was only a fraction of the total damage, but it emphasized the helplessness of individual farmers in dealing with conditions that affect entire land-use regions.

Even in New England, much of which is forest-clad or in pasture, there is preventable erosion. Perhaps the most serious and widespread damage in 1936 occurred in the cotton States from North Carolina to Oklahoma and Texas. Overcropping caused erosion in the Corn Belt and overgrazing and overplowing were main soil hazards in the Great Plains. In certain regions the cultivation of steep slopes and the practice of setting brush fires did great harm. In some localities the most urgent need is for engineering work such as terraces, check dams, ditches, and ponds, and in all localities there is need for adjustment in tillage practices. In some areas the problem is principally one of clothing denuded slopes with vegetation or of increasing the ratio of soil-conserving to soil-depleting crops. Everywhere, however, the problem has local peculiarities which interdict the use of blanket methods.

In the demonstration projects, 139 of which have been established in 41 States, the Soil Conservation Service begins by marking off a naturally bounded tract about 25,000 acres in extent. (There are three very large public-land projects in the Southwest and one in Wyoming, but these are not typical.) Next follow various soil and farm-management studies, including analyses of cropping systems and farm-income conditions. The results become the basis for a soil-conservation plan applicable to the demonstration area, to which the Soil Conservation Service gives effect by two principal means.

(1) It reaches an understanding with the proper public agencies that may be involved; then (2) it enters into 5-year agreements with private landowners. Each agreement contains a plan for land use and appropriate practices, specifies the assistance to be given by the Service and the proportion of the work to be done by the farmer, and obligates the operator or owner to maintain for the 5-year period any improvements that may be constructed and also to follow the agreed program of cropping and tillage. The Soil Conservation Service also draws up land-use programs for the entire area, including land not in farms as well as the land in actual cultivation.

Yet work of this type touches directly only the fringe of the problem. It covers only a fraction of the Nation's farm land, and directly involves a comparatively small number of farmers. Compared with what needs to be done, the amount of erosion control effected is very small. Research results and practical recommendations reach a wide audience through the extension services and find application on millions of farms in the national soil-conservation programs. Nevertheless much remains to be done. There is need for cooperation not only between the Federal and State agencies but between these agencies and local farm groups.

Soil Conservation Associations

Accordingly, besides conducting demonstration projects and carrying on similar work with Emergency Conservation Work camps, the Soil Conservation Service is encouraging soil-conservation associations, more than 400 of which have been organized already. Most of them are on or near areas where there are demonstration projects or where Emergency Conservation Work projects are under way. Membership in an association ranges from 10 to 400 farmers. It is entirely voluntary, and most of the associations have adopted articles of association without formal organization. They have the legal status of partnerships for limited purposes. Their members agree to live up to certain cropping and tillage practices and to cooperate in operations requiring concerted effort, such as the construction of terraces, check dams, ponds, and ditches.

There is a fundamental relationship between soil erosion and land-use practices on both farm and nonfarm land. It does not suffice to check erosion on farms here and there if other farms nearby continue to erode. Improper slope cultivation, with consequent heavy erosion, may ruin a whole valley lower down. In other words, the problem of preventing soil erosion is a social as well as an individual problem, and the soil-conservation associations rest on this principle. The organized farmers of an entire land-use area make a united attack on a problem which they could not solve individually.

In tackling the problem of the soil, however, voluntary organizations of the kind above described have obvious limitations. At the request of State agencies this Department has prepared a standard State conservation-districts law to serve as a recommendation regarding the nature of appropriate legislation, which, if enacted by State legislatures, would authorize the formation of public agencies with power to enter into agreement with farmers relating to the performance of appropriate control operations on eroding lands, and in case of majority vote, to establish land-use regulations. Texas has passed such legislation, providing authority to wind-erosion districts to expend funds and carry on work on lands not properly treated by the owners. In that State 14 conservation districts have been organized. Several other States are considering the enactment of similar laws at the next sessions of their legislatures.

The standard measure provides that proposed land-use regulations must be submitted to a referendum of the land occupiers and may not be enacted without a favorable majority vote. Once approved, the regulations would be binding on all lands within the district. There are provisions for notice, hearing, referenda, administrative appeal, and judicial review. No district could be organized without a majority in favor of it, and no specific regulation could be imposed without a referendum.

Boundaries of the conservation districts would be determined by a State soil-conservation committee, which could not act, however, until a petition had been filed with it by at least 25 farmers and until a public hearing had been held. The committee would fix the district boundaries by a State plan, drawn up to indicate the soil, the topography, and the types of farming. Once organized, the dis-

trict would have the authority to accept funds and services and otherwise to cooperate with Governmental agencies in the development of plans and programs for the district.

It would receive an annual appropriation from the State legislature, and technical and other assistance from both State and Federal agencies. It would have the power to make intensive studies of its territory and to contract with farmers for the performance of necessary control work. Wide adoption of this plan would provide the opportunity to develop erosion-control operations on an intensive local basis as a useful and, indeed, necessary complement to the more general agricultural conservation program instituted under the Soil Conservation and Domestic Allotment Act.

Land Use and Flood Control

In the Flood Control Act, which was approved June 22, 1936, Congress recognized the importance of land-use methods in flood control. Floods, of course, are erosion phenomena. They waste soil as well as water. The new law provides that Federal investigation of watersheds, measures for run-off and water-flow regulation, and measures for the prevention of soil erosion on watersheds shall be instituted by the Department of Agriculture. Studies and projects relating to the improvement of rivers and other waterways for flood control are the responsibility of the War Department. The act declares it to be the sense of Congress that flood control on navigable waters or their tributaries is a proper activity of the Federal Government in cooperation with the States and their political subdivisions, and that investigations looking to the protection of watersheds are in the general welfare. Thus the act emphasizes the complexity of the flood problem and points to the necessity for an approach to it from an agricultural as well as from an engineering standpoint.

LAND POLICY

It is coming to be generally recognized that the cornerstone of a sound national economy is a rational land policy. The droughts of recent years, with the resulting soil blowing and dust storms, have focused attention on the need of long-time land-use planning. Needless to say, wind erosion is not the only indication of the need. Forest devastation, the progress of soil erosion by water, the wide extent of submarginal farming on land unsuited to farming, the growing seriousness of tenure problems in many areas, and the prevalence of destructive cropping and overgrazing are a few of the problems which betoken the want of a coordinated land policy. Fortunately we have made a good start in recent years toward the development of a socially desirable land-utilization program.

The Resettlement Administration has begun to acquire poor farm lands and to promote their development for other uses. It has also aided farm people in some areas to find better locations. In the last fiscal year the Resettlement Administration obtained options on 9,500,000 acres of poor farm land in 207 projects. On the bulk of this acreage the Administration took up the options at an average price of about $4.50 an acre. Approximately $38,000,000 has been already allotted for the conservational development of these lands,

and the undertaking gave employment to as many as 55,000 relief workers.

Among the 207 projects 46 were sponsored by the National Park Service of the Department of the Interior. These will be developed for recreational purposes. The Bureau of Biological Survey has sponsored 32 of the projects for the propagation and protection of migratory waterfowl. The Indian Service has sponsored 31 projects to provide more land for Indians. The Resettlement Administration has sponsored 96 projects primarily of an agricultural character, though some of them include recreation, wildlife, and forestry aspects. In its resettlement activities the Resettlement Administration has approved 97 projects calling for the purchase of 730,000 acres of land and the building of homes for 13,255 families. Funds are now available for the construction of 40 of these projects. In addition there are 43 subsistence-homestead communities either completed or in process of completion.

As noted elsewhere in this report, the Bureau of Biological Survey has acquired considerable land for the preservation and conservation of wildlife. Prior to 1933 it had purchased 215,365 acres with funds appropriated to it by Congress. These lands formed the nucleus for 11 wildlife refuges, within which, however, additional lands were needed. Since 1933 the Biological Survey has purchased considerably more land with emergency funds made available through the Resettlement Administration. On July 1 about 893,000 acres in 42 refuge units had been, or were being, acquired at a total land cost of $5,359,254. Another important aspect of the national land policy is being developed under the Taylor Grazing Act, which Congress amended last year in important respects. One amendment enlarged (from 80,000,000 to 142,000,000 acres) the area of vacant unappropriated and unreserved lands of the public domain available for the creation of grazing districts under the act, which is administered by the Department of the Interior.

Land settlement, as well as the diversion of poor farm land to other uses, forms an integral part of the national land policy. Land settlement or resettlement will doubtless continue as long as we have suitable land available. Between 1930 and 1935, according to the Census of Agriculture, the number of farms in the country increased by approximately half a million. This is an indication of the extent to which farming has cushioned the shock of the industrial depression. Industrial workers have established many of the new farms in and near industrial centers, but a larger proportion of the increase has resulted from the fact that in the depression years the natural increase of the farm population could not find nonfarm employment. The new farms have developed largely on self-sufficing lines. Part-time farming underwent considerable development. Numbers of industrial workers acquired small plots near their work. They produced some of their own food and something to sell besides, and reduced their living expenses in other ways. Many suburban families started small-scale farming without moving. Some of them were able to rent land near their homes. This whole movement caused the census to classify as farms many places which previously it had not so classified.

Return Migration to Submarginal Lands

Another major type of recent land settlement is taking place on the poorer farm lands in several regions. In these areas, the chief of which are the southern Appalachian, the Lake States cut-over, and the Ozarks, considerable migration and farm abandonment had previously taken place. After 1930, however, many of the people who had gone away returned. They had lost their city jobs, and their former farm homes offered them at least a subsistence. But in some areas the part-time nonfarm work that had previously been available could no longer be obtained. Many lumbering and mining industries had collapsed. As a result the rural folk had to depend more than ever upon farming. The number of both part-time and full-time farmers increased. Furthermore, these areas have normally a high birth rate and there was no place for the rising generation to go. In consequence the rate of increase in the number of farms was greater in these areas than over the country as a whole. As a matter of fact, there was relatively little new settlement in the better commercial farming areas. In some such areas, indeed, as for example in central Indiana and Illinois, the farm population decreased, and farms became larger.

This tendency toward an increase in the number of farms in poor farm areas inevitably created difficult problems. It is not an easy matter to start a new farm and get it well established even in good times. In hard times, particularly where the land is poor and where the settlers have little money, the obstacles are greater. Many farmers who returned to their former homes, or who took up other land, found themselves unable to make ends meet.

Small, poor farms inadequately stocked and equipped do not furnish an easy livelihood, and the occupants will be quick to move when better prospects appear. The Resettlement Administration is studying the problem and, where possible, is providing opportunities for the relocation of farm families on land better suited to their needs. The creation of new farms in regions of poor land, where soil depletion is serious and where the standard of public services is low, simply means the creation of rural slums. The new farms established in the last few years have commonly been smaller and poorer than the old ones, and sufficient additional part-time work can seldom be had. Resettlement alone cannot cure the trouble, though it may help. More is to be hoped for from the revival of industry, which will tend to lessen the pressure of population on the land; but unless employment opportunities in industry can be stabilized we shall continue to face the problems created by the periodic swings of a large segment of our rural population back and forth between country and city, moving cityward in good times and countryward in periods of depression.

The development of better land use is largely dependent on the improvement of land-tenure systems. Most people now recognize that not all the land should be in private hands. Public ownership is better for parks, for various recreational uses, for wildlife refuges, and frequently for forests. Certain types of grasslands, as well as forest lands, can be best managed as public property. These facts,

which scarcely anyone now denies, do not warrant going to extremes in the public ownership of land resources. They simply indicate that the public ownership of land has a place in a good land system, and that tradition and custom should not be allowed to block reform.

There are good and bad methods of private ownership. Certain widely established practices stimulate unwise speculation, soil mining, absentee landlordism, and excessively high rates of tenancy. These are not the inseparable and unavoidable results of private ownership. Methods can be developed which tend to minimize them, as the experience of some other countries amply demonstrates. Our traditional land-tenure system has shortcomings which can be remedied without changing its fundamental character. But it is necessary to recognize that there are different types of land, some of which can best be used as private property and some of which can best be used in public ownership.

Conditions Peculiar to United States

It is necessary also to recognize that the tenure practices developed in this country are not the only practices available. Our methods of private ownership have developed tenancy conditions very different from those of some other countries. Thousands of our farm tenants change their farms every year, and thousands more have only the semblance of security in their tenure. Few tenant farmers, except those who occupy the farms of relatives, can be sure of operating their farms for longer than the period covered by the lease, which is generally for only one crop-year. Moreover, they have no stake in any improvements which they may make on the farms. If they keep the buildings and equipment in good repair and build up the soil through good tillage or the application of fertilizer, or if they prevent erosion by terracing or other methods, they may have their rent raised. Should they be forced to leave they will not be compensated for the improvements. This fact discourages tenants from making farm improvements and from conserving the soil. The new Soil Conservation and Domestic Allotment Act is seriously handicapped in its application to tenant farmers by these difficulties.

Other countries have taken steps to reduce tenancy or to change and improve it, and eventually the United States must do the same. It must face the problem of providing security for its great mass of landless farm people. The farm census of 1935 reported about 2,865,000 tenant farmers, whose families aggregated 12,500,000 people. This was the largest number of tenant farmers ever reported by the census. In most States the percentage of tenancy increased significantly between 1930 and 1935. In certain areas more than two-thirds of the farm operators are tenants. Many of them frequently shift from farm to farm to the injury of the land, to the deterioration of community institutions, and to the decline of their own morale. Also, our farm population includes several million farm laborers, a large proportion of whom lead a migratory life, with only casual and uncertain employment. This group, as well as the tenants, should be considered in our land policy.

This Department, in cooperation with the Resettlement Administration and other agencies, is studying ways and means of improving

138904°—37——3

the tenancy system. The problem is national in scope and of tremendous importance. In some areas an acceptable remedy would be a more widespread diffusion of farm ownership provided such ownership can be protected from the worst vicissitudes of our economic life. One of the Resettlement Administration's projects seeks to aid 1,000 southern tenants to become farm owners. Then there are ways of improving leasing agreements. It should be possible to do so with advantage to landlords as well as tenants. The problem is to reshape our land-tenure system so as to promote a type of agriculture calculated to conserve the soil, to give the cultivator a more secure occupancy of his farm, to maintain the existing capital investment in farm buildings and farm improvements, and to promote the development of sound rural institutions. Most of the necessary steps will require legislative action, both State and Federal. The whole problem requires statesmanlike treatment.

Farm-Land Values

Farm-land values increased for the third successive year during the year ended March 1, 1936. This gain, of course, reflected continued improvement in agricultural conditions. Not only were valuations higher, but the farm-land market indicated increased interest on the part of prospective farm buyers, particularly in the East North Central and Pacific States. The number of farms purchased increased considerably. With the equities of farm owners rising, loan companies showed more willingness to finance sales; sellers raised their asking prices, and creditor agencies found themselves able to dispose of more farms. Tenants showed a definite interest in buying farms.

This Department's index of the value per acre of farm real estate rose during the period mentioned from 79 to 82 percent of the pre-war level. Gains were far more general than in either of the 2 preceding years. All States but two reported some increase. During the preceding year only 31 States reported rising values. As a group the Corn Belt States reported the greatest average increase, nearly 8 percent. States in the wheat region and grazing area of the West averaged 5-percent gains. The Cotton Belt States averaged 3 percent; the hay and dairy States averaged 2 percent. For 11 States the index was above the pre-war basis. Four of these States were in New England; one in the Middle Atlantic group of States; five in the South, and one on the Pacific coast.

There were favorable changes in the frequency of transfer. For the country as a whole the number of farms transferred as a result of debt difficulties was a little smaller than during the preceding year, though the decline was not uniform. In fact, in a number of States such transfers increased. For the country as a whole, however, forced transfers associated with debt declined from an estimated frequency of 21.0 to 20.3 per thousand of all farms. The number of voluntary transfers showed a definite upturn and reached levels comparing favorably with those of the years immediately preceding the depression. This gain, though somewhat encouraging, did not indicate that a wholly normal farm real-estate market had become reestablished. Creditor agencies still had many farms which

they were anxious to sell. Nevertheless, the emergency phases of land financing declined in importance.

From the standpoint of the individual farmer attention now shifts to making good on present loans and to securing normal financing at reasonable cost. The Farm Credit Administration is giving substantial help. Its activities in refinancing, in the deferring of payments on principal, in the granting of extensions in facilitating the handling of distressed mortgage debts, and in reducing interest costs to farmers are important factors in the improvement of the farm real-estate situation, as well as in the improvement of agriculture as a whole. How effective this work has been can be seen in the decline in the number of farmers who need aid in preventing foreclosures and also in the decline in the number of extensions granted. Also, collections on loans held by the land banks are improving. The important task now is to develop a farm-mortgage system that will be more nearly shock proof than the system that existed before the depression.

FOREIGN TRADE IN FARM PRODUCTS

Farm products participated in the general increase which took place during the past fiscal year in all branches of United States foreign trade. This was true both of farm imports and farm exports, in spite of certain distorting influences that tended to enlarge the imports and diminish the exports. Chief of the abnormal forces was the persistent effect of the 1934 drought and a flight of capital into the United States from other countries. General business recovery, together with the influence of the reciprocal trade agreement program, benefited the farm export trade materially.

Exports of United States farm products rose from 669 million dollars in the fiscal year 1935 to 767 millions in 1936. Imports of farm products (including coffee, rubber, silk, and many other exotic products) rose from 971 million dollars in 1934–35 to 1,185 million dollars in 1935–36. As compared with the low points of 590 million dollars in exports and 612 million dollars in imports during 1932–33, the increases seem large, but neither the exports nor the imports of farm products were near the levels maintained from 1920 to 1929.

Substantially larger shipments of cotton, tobacco, and fresh and dried fruits were mainly responsible for the improvement in the exports. Our exports of cotton, including linters, totaled 6,702,000 (500-pound) bales, as compared with 5,328,000 bales the preceding year. Leaf-tobacco exports amounted to 417,539,000 pounds, against 353,347,000 pounds the year before. Improvement in the exports of fresh and dried fruits, practically all classes of which showed substantial gains, was in part a result of foreign duty reductions brought about under the reciprocal trade agreement program. Exports of lard, cured pork, and wheat, continued to reflect the reduction in supplies caused by the drought of 1934 and by heavy rust damage to wheat in 1935. Lard exports fell to the lowest figure in recent years. There were practically no exports of domestically produced wheat.

An important part of the increase in the agricultural imports was the so-called competitive products. It is necessary to distinguish

between products like sugar and wool, of which we regularly import a great part of our supplies, and products such as corn, wheat, and rye which we import in significant amounts only under exceptional conditions. Most of the increase after 1932 in the value of our competitive agricultural imports was in the regularly imported items, which tend to be imported in greater quantities as economic conditions improve. But some of it in the last fiscal year was in grain and feeds, meats, dairy products, and eggs, the domestic production of which had been reduced by the 1934 drought. Imports of this character reached their peak during the first quarter of the fiscal year and then declined. The 1936 drought may again increase the imports of these products.

Another important distinction exists between noncompetitive imports and imports similar to commodities produced in the United States. Our total agricultural imports in 1935 amounted to 1,073 million dollars.[1] Of this amount 483 million dollars, or 45 percent, consisted of noncompetitive items, like coffee, rubber, raw silk, bananas, spices, cocoa, and tea. There remained 590 million dollars' worth of imports similar to or capable of being directly substituted for our own agricultural products. About 134 million dollars' worth of sugar came in under strict quantitative limitations and cannot properly be deemed competitive. Subtracting the sugar leaves only 456 million dollars in competitive imports, or about 42 percent of the total of all agricultural products imported during the calendar year 1935. This total may be compared with our farm export total of 747 million dollars during the same period.

Significance of Competitive Imports

Despite the domestic shortage of certain farm products, our imports of competitive commodities were less than two-thirds as high as the annual average for the decade preceding the depression. In most cases they represented an insignificant proportion of our normal output of similar products. They fell far short of offsetting the deficits left by the drought. Imports of corn in 1935 amounted to only 1.7 percent of our average annual corn production from 1928 to 1932. Wheat imports were 3.2 percent of the average production, oat imports only 0.8 percent, barley imports 4.7 percent, pork imports 0.1 percent, and beef imports of all kinds only 3 percent.

The drought of 1934 caused a reduction of 50 million tons from our average production of feed in the United States. In the year and a half from July 1934 to December 1935, imports of feed and fodders of all types amounted to less than 3½ million tons, or only 7 percent of the shortage. Imports made up only a trifling part of the loss in production caused by the drought. The same was true of wheat, meat, and dairy products. Farmers met the feed shortage not primarily by imports, but by lighter feeding of animals, earlier and heavier pasturing, and heavy marketing for slaughter.

As a result of this year's drought we may have to import some feed. This is the logical procedure, good for both producers and consumers. Agriculture's problem is not how to stop a moderate

[1] Excluding distilled liquors.

flow of competitive imports following a crop failure but how to plan for its normal conditions, which are those of a surplus country. Normally, American agriculture encounters its major foreign competition abroad. It produces for export; and temporary shortages induced by drought should not hide the fact that an import-exclusion policy would react adversely on the export trade. Besides hurting the farmers, who must purchase feed in short-crop years, such a policy would permanently injure those who grow cotton, tobacco, wheat, hogs, and fruit.

In the balance of international payments of the United States for 1935 the increase in imports, which consisted of agricultural products brought in to relieve the drought emergency, tended to obscure the persistent unbalance between our import and export trade. As a result of these unusual temporary imports, our excess of exports was only $236,000,000. While that figure is at about the level of the balances during 1932 and 1933, it is lower than that for any other year since the World War. The apparent approach of our merchandise trade to an approximate balance, however, is illusory. It will probably be reversed as soon as we have normal crops unless the trade-agreements program greatly increases our imports of foreign industrial specialties. The largest single factor in the balance of payments for 1935 was the continuing flight of capital from Europe and elsewhere to the United States. This movement of capital tended, of course, temporarily to hide the necessity for increasing our imports.

Reciprocal Trade Agreements

Agriculture is beginning to benefit from the Reciprocal Tariff Act. During the last fiscal year the United States concluded reciprocal trade agreements with nine countries, namely, Colombia, Canada, Honduras, the Netherlands, Switzerland, Nicaragua, Guatemala, France, and Finland. It had entered previously into similar agreements with Cuba, Brazil, Belgium, Haiti, and Sweden. All 14 agreements are in effect except those with Finland and Nicaragua.

It is difficult to measure the results as yet. Most of the agreements have not been long in effect and the period covered by their operation has been one of abnormally low production in the United States. Moreover, the countries with which agreements have been concluded ordinarily take only about a quarter of our total agricultural exports. It will not be possible fully to test the reciprocal trade-agreement program until agreements have been concluded with one or more of the countries that constitute our leading foreign markets, namely, the United Kingdom, Germany, and Japan.

Foreign countries have made important concessions on United States agricultural products. The agreement with Cuba substantially reduced that country's duties on American lard, potatoes, rice, and many other products. Canada reduced its duties on cured pork and lard and on a long list of fruits and vegetables. European concessions include lower import duties and larger import quotas on a long list of commodities and are particularly helpful to our fruits. France has made important concessions as well on American tobacco, and several countries have relaxed their restrictions on imports of American lard and wheat. Cotton, our leading agricultural

export, can benefit only indirectly from the trade agreements, because the foreign countries with which tariff reductions can be obtained through such agreements do not impose serious restrictions on cotton. Most of the countries with which agreements have been concluded admit our cotton either duty-free or at low rates.

The reciprocal concessions which the United States has made help our exports by aiding foreign countries to get dollar exchange. We have made a few concessions on agricultural products. Few of them, however, were in effect during recent increase in agricultural imports. Negotiating the agreements the United States has kept two principles in mind: (1) That the import duties should not be reduced below the rates prevailing prior to the enactment of the disastrous Tariff Act of 1930; and (2) that on products of primary importance the reductions should be safeguarded either by seasonal limitations or by import quotas.

In the Cuban agreement, for example, the duties on vegetables are reduced for a limited period during which our own supplies are small. In the Canadian agreement the duty reductions on cattle, seed potatoes, and cream apply to strictly limited quantities. The only important agricultural items on which duty reductions have been made without some such safeguard are various types of cheese and imported wrapper tobacco. But the duties on cheese have not been reduced below the rate prevailing previous to the Tariff Act of 1930, and most of the types of cheese concerned are not produced commercially in this country. As for wrapper tobacco, few American farmers grow it, while many thousands produce the filler and binder tobacco which has to be combined with the imported article.

Concessions by the United States

Most of the tariff concessions made by the United States are reductions on specialized industrial items or agreements to keep on the free list noncompetitive products such as coffee, cocoa, and bananas. Other countries have made concessions to us on industrial products; and the advantage goes to American farmers as well as American manufacturers. Increased industrial exports mean more buying of farm products.

Broadly speaking, there are three types of reciprocal-trade agreements: (1) Bilateral arrangements for the exchange of exclusive concessions with individual countries, (2) arrangements based on conditional most-favored-nation treatment, and (3) arrangements based on unconditional most-favored-nation treatment. The United States has favored the third method, and it may be useful to glance at the reasons.

(1) The strictly bilateral approach is open to the objection that it would reduce our foreign trade. In our trade with most countries we export more than we import. To equalize matters with these nations individually would require a reduction in our exports. This has been the experience of European countries that have tried to achieve bilateral balances of trade. Under our present policy triangular and multiangular trading squares matters. It enables countries that buy more than they sell here to even things up by transactions with other countries which in turn may divert products to the United States.

(2) Under the second approach, the conditional most-favored-nation treatment, reciprocal concessions might be granted to countries that made equivalent concessions to us. But this method, too, tends to decrease the total trade. Few countries other than the parties to an agreement will be equally interested in the same commodities and duty reductions. Most countries will therefore be unwilling to make the equivalent concessions required. Moreover, they will object to discriminatory tariff treatment and may retaliate with higher duties against our goods.

The result may be a tariff war and new obstacles to international trade. Even without retaliatory measures discriminatory treatment under the conditional principle may force trade into more restricted channels. Changes in foreign trade affect the domestic markets.

(3) The third or unconditional most-favored-nation approach has been followed by the United States in all cases except that of Cuba, under the present trade-agreement program. This is the policy required by the Reciprocal Trade Agreements Act, which directs the Government to grant any tariff reductions to all countries except those that discriminate against the commerce of the United States. Under this last restriction Germany and Australia have been denied the benefit of most-favored-nation treatment, but all other countries receive it. The unconditional most-favored-nation treatment, which has been followed by the United States since 1922, has the great advantage of affording a guarantee of no discrimination against us in our foreign markets.

In negotiating the Brazilian agreement the United States did not get a reduction in the Brazilian duty on wheat flour. Subsequently, however, the Brazilian Government reduced its flour tariff on its own initiative. The unconditional most-favored-nation clause in our trade agreement with Brazil gave the benefit of this reduction automatically to the United States, as well as to other countries. Conversely, Germany has been unwilling to come to an unconditional most-favored-nation understanding with the United States. As a result we have lost part of our market for agricultural products in that country.

What Should We Import?

In deciding the kind of imports that we should encourage under reciprocal-trade agreements it is important to remember that the United States tariff has had its greatest effect in the past in preventing imports of industrial products, and therefore in raising the prices of the things that farmers buy. The domestic market for most industrial products is relatively elastic, whereas the domestic market for most agricultural products is relatively inelastic. Many existing tariffs merely serve to bolster industrial monopolies, which use their advantage to obtain high prices. The major markets for United States farm exports are to be found in industrial producing countries such as Great Britain, Germany, and Japan. If the trade-agreements program is to go forward successfully we must conclude agreements with the large industrial countries and offer reductions in our duties on manufactured products.

THE 1936 CROPS

The year 1936 ranks next to 1934 as the most disastrous season for crops in the history of the country. Records going back to the early 1860's include no seasons comparable with 1936 and 1934 in loss of acreage and reduction of yields. Both years brought great droughts. This year's drought reduced crop production to about one-fourth less than the usual output; whereas the drought of 1934 reduced it to about one-third less.

Geographically, there was a striking resemblance between the two droughts. They were particularly severe in the whole area stretching from North Dakota and eastern Montana to north-central Texas, and extending eastward over Missouri, southwestern Illinois, southern and western Iowa, and west-central Minnesota. Northeastern Wyoming, parts of eastern Colorado, northeastern New Mexico, and northwestern Arkansas also suffered severely in both years. In both seasons the production of wheat, corn, oats, barley, rye, and grain sorghums was greatly reduced; but in 1936, except in limited areas, there was no repetition of the acute shortage of hay and roughage that caused so much trouble in 1934.

Corn production in 1936, as a result of the drought, was slightly smaller than that of 1934 and was the smallest corn crop harvested since 1881, when our population was only 40 percent of what it is today. Of the eight States which usually produce two-thirds of the total corn crop seven had even less rainfall during the summer months than they had in 1934. The corn crop was particularly poor in the Dakotas, Nebraska, Kansas, Missouri, and Oklahoma. In these States the acreage that could be harvested for grain was largely limited to the river bottoms, to areas favored by local showers, and to irrigated sections. Much of the crop was cut early for forage and silage or was pastured by livestock. Grasshopper damage was severe in some areas and in these localities crops had little value even for fodder. Present indications are that the total corn crop is only about 1,458,000,000 bushels as compared with an average of 2,553,000,000 bushels for the period 1928 to 1932.

About one-fourth of the acreage seeded to winter wheat was a loss as a result principally of drought conditions. Scarcely more than half of the seeded spring wheat acreage was harvested for grain. The total wheat production was only about 630,000,000 bushels. This is more than was produced in any of the preceding 3 years, all of which were very unfavorable, but less than the production of any other year since 1917. Rye suffered likewise. Abnormally high temperatures and drought combined reduced oat yields in practically all the important oats-producing States except those along the Pacific coast, and in some States caused nearly a total loss of the crop. Oats production is estimated at 777,000,000 bushels, or about two-thirds of the usual production. However, it was about 43 percent greater than the very short oat crop of 1934 and slightly above the crop of 1933, though below the production in any other year since 1896. The barley crop was reduced by one-half. It is estimated at 145,000,000 bushels, as compared with 282,000,000 bushels in 1935. Production of grain sorghums is estimated at 59,000,000 bushels, as compared with 97,800,000 bushels in 1935.

The Feed-Grain Supply

Production of corn, oats, barley, and grain sorghums combined is only about 58,000,000 tons, as compared with 93,000,000 in 1935, and 54,000,000 in 1934. In other years since the World War the combined production of these grains has averaged 100,000,000 tons and has ranged from 85,000,000 to 117,000,000. Reserves of grain on land will be closely utilized and net imports of grain and feedstuffs may have to be increased somewhat; but most of the shortage will be met by feeding hogs less grain than usual.

There is a fair supply of hay and roughage. Hay production is only about 10 percent below the average. In 1935, three-fourths of the States had hay crops above the average, and the supply of old hay on farms at the beginning of the season was rather large. But many farmers had to use some of their old hay this summer. By utilizing straw, fodder, and other roughage a little more closely than usual and by using part of their reserves, farmers will be able to feed nearly the usual quantity of hay per unit of livestock.

Rice, sugar beets, and irrigated crops generally gave good yields. So did cotton and peanuts east of the Mississippi River. Tobacco, with yields about the average, was moderately light, drought having prevented expansion of the acreage. The buckwheat crop was the smallest since the Civil War. Drought damaged it severely in practically all producing States. Flaxseed production, though greater than in 1934, was below that of any other season in 60 years. Potato production was below average and sweetpotatoes about an average crop. As noted elsewhere in this report there was a fair supply of commercial vegetables and a light pack of most canning vegetables except tomatoes.

WEATHER CONDITIONS OF 1936

Weather conditions in the United States in 1936 were extremely abnormal. During the spring months they produced unprecedented floods in the Eastern States, bad dust storms in the Middle West, and destructive tornadoes in the South. Later the most severe drought of record developed in the interior States. The drought was the third in recent years, others of tremendous national significance having occurred in 1930 and 1934. This year's drought, besides causing enormous damage to crops, inflicted great hardship on farm people throughout an immense area, particularly in States that had not recovered from the drought of 1934. It aroused fears among some people that our climate might be undergoing a permanent change, though there is no scientific evidence that such is the case, and led to speculation as to whether recent conditions might possibly be due to some human activity. Various suggestions for preventing drought have been made. In general these suggestions fail to distinguish between basic changes in climate and proposals for mitigating or preventing some of its untoward effects. It will be interesting, after glancing at what the weather did to us in 1936, to notice what meteorological science has to say about the causes of floods and droughts—for both floods and drought have a common origin in the natural laws that govern evaporation and precipitation.

The floods in the Eastern States followed a severe winter, accompanied by the heaviest snowfall in many years in the country north of the Potomac, the Ohio, and the Missouri Rivers. Mild, rainy weather late in February and early in March caused rises and ice gorges in the rivers of New England and the Middle Atlantic States. About March 17 heavy rains fell on well-saturated and semifrozen soil, and the percentage of run-off was unusually high. Moreover, the northern rivers were at or above flood stage, and those in Maryland and Virginia, while not in flood, were higher than normal.

The result was disastrous floods in the James, the Potomac, the Susquehanna, the Connecticut, and the Merrimack Rivers, in some of the tributaries of the Ohio River in Pennsylvania, and in the Ohio from Pittsburgh, Pa., to below Wheeling, W. Va. The Ohio River flood gave a record crest stage of 46.0 feet at Pittsburgh on March 18. The previous high-water record was 38.7 feet on March 15, 1907. Flood damage in the Northeastern States was undoubtedly the greatest of record. Many houses were destroyed, and business was partially or completely paralyzed in many industrial areas. Losses to wage earners and retailers were heavy.

The weather of 1936 was decidedly unfavorable for agriculture over the greater portion of the United States. Precipitation in the winter and early spring was very scanty in the Southwest, where the soil became extremely dry, and severe dust storms caused much damage. In May, however, there came abnormally heavy rains, which were especially helpful to winter wheat over large areas, particularly in Kansas. Other parts of the country were less fortunate. Serious conditions developed over large areas. Dry weather in May and June brought widespread damage to early truck, hay, and pastures.

Spring Exceptionally Dry

The spring was the driest of record in many southeastern localities. Great harm resulted to early crops in considerable areas, especially from North Carolina southward and southwestward to central Alabama. The winter-wheat crop, however, was not seriously affected, principally because of May rains in the western portion of the Wheat Belt and comparatively cool weather in the eastern part. Some deterioration of the crop occurred, especially in northern districts. The spring-wheat crop and other small grains in the Northwest were severely damaged. The livestock situation became desperate. Over large areas there was neither feed nor sufficient water available. However, conditions continued favorable in the North Pacific States.

The summer was abnormally hot and dry in all Central and Northern States between the Appalachian and Rocky Mountains. July had less than 10 percent of normal rainfall in considerable areas; there was less than half of normal (usually much less) in the western part of the Ohio Valley, the Great Lakes region, the upper Mississippi Valley, and throughout the Plains from Oklahoma northward to North Dakota and Montana. The States from Oklahoma northward to North Dakota had only from 20 to 36 percent of normal; Minnesota had about 20 percent; and Iowa less than 15 percent. July 1936 was drier than July 1934 in every State from Kentucky, Missouri, and Oklahoma northward to the Canadian border.

The months of June and July combined had an average of only about one-third of normal rainfall in the Plains States and about 40 percent of normal in the western Ohio and middle Mississippi Valleys. In the interior States the 2-month period was much drier than the same 2 months during the great drought of 1934. Abnormally high temperatures aggravated the effect of the deficient moisture.

The 4 months of the growing season up to the end of July were the driest of record in the Dakotas, Minnesota, Wisconsin, Iowa, Missouri, Illinois, and Indiana, and the second driest in Ohio, Kentucky, Oklahoma, Kansas, and Montana. Of the Central and Northern States between the Appalachian and Rocky Mountains, only Michigan, Kansas, and Nebraska were drier in 1934 than this year for these 4 months.

The weather during August, for the most part, continued decidedly unfavorable throughout the central valleys, with afternoon temperatures in many places reaching 100° F. or higher nearly every day. Lower temperatures and rather frequent showers were decidedly helpful in northern sections from New England westward to the Great Plains, including considerable portions of the eastern and northern Ohio Valley and some upper Mississippi Valley sections. However, during this month the drought extended southward to Texas, Arkansas, northern Louisiana, Mississippi, and Tennessee.

THE CAUSE OF DROUGHTS

There are two basic principles in rain production—evaporation which charges the air with moisture, and condensation, which releases it. The first is important, but the latter much more so in connection with droughts. The only way rain can be produced in appreciable amounts is by the air, including the invisible vapor of water, becoming cooled on a large scale. Cooling causes condensation because warm air can hold more moisture, more water vapor, per unit volume than cool air. The capacity of air, or rather of space, for holding invisible moisture doubles with each increase of 20° F. in temperature. Thus, a cubic foot of saturated air at 80° F., if cooled down to 60° F., must lose by condensation half of its water content, which appears as cloud and rain.

Air cools when rising because it comes under less and less pressure, and therefore expands; the normal fall in temperature for an ascending column of air is 1° for each 183 feet of rise. Nature effects this method of cooling in a number of ways, usually on an immense scale. Air moves from place to place over the earth's surface in mass formation. These masses come from two main regions—polar and tropical. Those from the Poles are dense, heavy, and relatively cold; those from the Tropics are warmer and lighter.

When polar and tropical air masses meet, the tropical air, being lighter, naturally flows up over the opposing dense air, just as it would flow up a mountain side. As it ascends it expands and cools, and the water vapor is cooled enough to condense and fall as rain. Cooling the water vapor in this way is nature's method of producing rain in appreciable amounts. It is the only effective way.

When the normal courses of these opposing air masses are disrupted for a considerable period, abnormal conditions, such as

droughts, result. These processes have a world-wide relation. Nature's weather factory is the whole world, and some of its operations have not yet been discovered. Just how and why these abnormal conditions establish themselves and persist so long, meterologists have not determined. Enough is known, however, to make ridiculous any suggestions that men can basically change the order of things.

New Methods in Weather Forecasting

It has become practicable during recent years to supplement empirical methods of weather forecasting, as developed in the nineteenth century on the basis of experience alone, with rational procedures based on an understanding of the physical processes involved; and as a result, weather forecasting has for some time been developing along sound physical lines, though for a long time it must continue to be a combination of physical reasoning with methods based on accumulated practical experience with synoptic charts.

Modern contributions to the difficult problem of weather forecasting are being actively studied and tested in the meteorological services of the United States and other countries, and the Weather Bureau is keeping informed on all important developments in this field. During the fiscal year 1936 substantial progress was made in developing air-mass analyses and applying them in forecasting.

In air-mass analysis attention is primarily directed to the great streams of air that are present over a given region and are composed of masses of air of different origin, properties, and motions, separated from one another by more or less pronounced discontinuities. The analysis of the synoptic map consists of the identification and delimitation of the different air masses, the determination of their motions and physical properties, and the relations of the weather phenomena to the physical processes operating.

To develop an adequate and effective working procedure in this analysis, to articulate it with the other work of the Weather Bureau, and to amalgamate it with the accumulated knowledge and experience gained in the past, requires prolonged study and trial. The work now being carried on is designed to develop, as quickly as possible, a satisfactory and workable technique. It has continually been made of greater and greater assistance to the official forecasters, who utilize it more and more in their work.

During January 1936 Sverre Petterssen, of the Norwegian Meteorological Service, conducted a series of lectures and conferences at the central office of the Weather Bureau on the physical analysis of weather maps (by the principles of air-mass analysis and also by certain principles based on the kinematic theory of fluid motion), and on weather forecasting. The analysis of maps and the making of forecasts are two quite distinct things; and Dr. Petterssen's investigations have dealt particularly with the step from analysis to forecast. Great benefit to the work of the Weather Bureau has resulted.

In addition, a limited amount of research work on several problems involved in air-mass analysis and its practical applications has been done—particularly a preliminary study of the physical phe-

nomena leading to the development of the severe cold waves which often enter the United States from Canada.

The past 7 years have been characterized by extreme heat and widespread droughts in summer, wind and dust storms of unprecedented violence, damaging floods, and during 1935–36, extremely low winter temperatures extending over wide areas of the country. As a result of these abnormal weather conditions thousands of human lives have been lost, millions of dollars worth of property has been destroyed, and the income of many farmers has been wiped out or greatly reduced. The need for pursuing research studies looking toward the making of long-range weather and crop predictions is more apparent today than ever before. If there is one chance in a hundred of discovering the causes of abnormal weather, the effort is worth making, for agriculture, business, and the whole Nation would gain thereby.

Projects Under Bankhead-Jones Act

Under the Bankhead-Jones Research Act two lines of work have been undertaken. One, in which the Weather Bureau, the Bureau of Agricultural Economics, and meteorologists of Harvard University and the Massachusetts Institute of Technology are cooperating, is a survey and critical appraisal of methods now employed in attempts at long-range weather forecasting by foreign countries and by private individuals and agencies in this country. This survey should give a basis for research projects to be carried out during the fiscal year 1937 and thereafter. Certain statistical investigations also are being carried on concerning planetary and lunar relationships with terrestrial weather, and periodicities in weather and solar phenomena. The other study is concerned with the relationship between weather and crop yields and involves the cooperation of several bureaus of the Department, such as the Weather Bureau, the Bureau of Plant Industry, and the Bureau of Agricultural Economics, and also the assistance of a number of State agricultural experiment stations. From these preliminary studies the Department expects to develop more intensive research in crop-yield variations and weather factors during 1937 and subsequent fiscal years.

Comprehensive soil, phenological, yield, and weather data have been collected from experiment-station records in nine North Central and two Middle Atlantic States and from records of the dry-land farming stations of the Bureau of Plant Industry. Statistical technique is being developed for determining the validity of combination or segregation of yield series of different rotations, soil treatments, variety tests, etc., in order to form series that may be used in measuring crop-yield responses to fluctuations in weather phenomena. Most weather-crop research to date has been on an extensive scale geographically; averages of crop yields and weather by States and regions have been studied. It is believed the present, more intensive approach will lead to greater knowledge of the basic laws involved. A beginning has been made in the evaluation of work previously done in this field.

Under the Bankhead-Jones Research Act a project has been set up in the Bureau of Agricultural Economics in cooperation with

Harvard University to provide for the study of relationships between solar and terrestrial phenomena, especially relationships having a bearing upon long-range weather forecasting. Equipment is being designed, using the principles of telephotography, for making daily observations of the sun's corona. Heretofore measurements of this important indication of changes in solar activity have been possible only at infrequent times of complete eclipse of the sun.

In addition the Weather Bureau, with an allotment of funds from the Works Progress Administration, has continued its investigations begun with funds assigned it by the Civilian Works Administration. This work consists in computing correlations between conditions in the United States and precedent conditions in foreign countries. So far correlations have been completed between temperatures by quarters in 12 districts of the United States and pressure conditions at 60 foreign stations distributed throughout the world, both in the Northern and Southern Hemispheres. The time intervals employed were 3, 6, and 9 months. The survey of rainfall conditions in the United States as compared with precedent pressure conditions at the 60 foreign stations is rapidly nearing completion. It is planned next to compute corrrelations between foreign temperatures and foreign rainfall with subsequent temperature and rainfall conditions in the United States.

MEASURES FOR DROUGHT RELIEF

With other Government agencies both Federal and State, this Department cooperated in measures for drought relief. It so modified the soil-conservation program as to make allowance for conditions beyond the control of the farmers; issued supplementary provisions to increase the production of feed and forage; encouraged the planting of emergency forage and hay crops; and in general enabled farmers in drought areas to take advantage of the income-insurance features of the program. The Government's readiness to make purchases of livestock from drought areas protected markets against sharp declines. Loans for the purchase and storage of seed enabled farmers to prepare for the next crop. An agency established at Kansas City facilitated the movement of feed into drought-stricken areas and also the movement of livestock from drought areas to localities where surplus feed and pastures were available.

Under the surplus-removal clauses (sec. 32) of the amended Agricultural Adjustment Act, quantities of food and feed became available for relief in drought States. Between June and September the shipments included 1,171 carloads of foodstuffs for human consumption and 375 carloads of millfeed for livestock. Some shipments of this kind would have been made in any case; but the drought emergency necessitated a considerable increase in shipments to drought areas. The Resettlement Administration made loans and grants to farmers for the purchase of feed, seed, forage, and food; the Works Progress Administration provided employment to farmers in road construction, in well digging, and in building small dams and reservoirs. The Farm Credit Administration alleviated credit difficulties, and the Federal Surplus Commodities Corporation carried

out a small-grain seed-conservation program. Western and Middle West carriers reduced freight rates on feed and livestock.

Beef-cattle numbers were more nearly in balance with feed supplies and with market requirements than they had been during the drought of 1934. Indications were that prices would be favorable to producers in 1937. There was no need, as there had been in the previous emergency, for the Government to buy several million head of cattle. It purchased only enough to prevent sharp price declines, and restricted the purchases to the classes and grades of cattle least suitable for resale as stockers and feeders and least desirable for breeding herds. It disturbed the commercial cattle trade as little as possible and encouraged a movement back to the country for feeding and breeding.

The A. A. A. began purchasing cattle in the drought area on August 3, when market receipts above normal requirements caused a decline of prices. It made limited open-market purchases at terminal markets serving the drought territory. Up to September 4, however, it had purchased only 2,964 head. By that time fall rains in parts of the drought territory had encouraged farmers to retain cattle and had increased the demand for feeder stock. Funds available under section 32 of the amended Agricultural Adjustment Act provided the means for purchases of surplus livestock. The payments to farmers and ranchers were purchase payments only; they did not include additional benefit payments, as the cattle and sheep purchases in 1934 had done. Meat resulting from the buying programs went to the Federal Surplus Commodities Corporation for relief distribution.

Seed-Grain Situation

There was a shortage of small grains suitable for seeding in the drought territory. The seed-grain purchase program helped to prevent an acute deficiency and to obviate the planting of light and undesirable seed in 1937. It provided for an advance of not more than $10,000,000 to the Farmers' National Grain Corporation, a farmers' cooperative, for the purchase of between 7,000,000 and 9,000,000 bushels of spring wheat, durum wheat, oats, barley, and flax. Seed grain thus acquired will be sold to farmers at reasonable prices before seeding time in 1937. Supervised by the Federal Surplus Commodities Corporation, the seed-purchase program included efforts to conserve and store desirable seed stocks.

It became evident in September that little corn suitable for seed in the western and north-central part of the Corn Belt will be available for the year's crop. Reports from large sections of the western Corn Belt indicated it would be necessary to get from 2,000,000 to 3,000,000 bushels from other localities outside the worst drought-stricken sections. As a means of guarding against a shortage of adaptable varieties, the Government offered two types of non-recourse loans on farm-stored seed corn. One type made available a loan of $1.75 a bushel on field-selected corn having proper germination and storage qualities. The other offered a loan of $0.55 a bushel on good quality and properly stored crib corn, suitable for sorting at a later date. Each loan note gave the Government a purchase option

amounting to $3.50 per bushel on the field selected and $1.50 a bushel on crib-selected corn, shelled and graded in the sack.

It proved difficult for the railroads to grant blanket reductions in freight rates on shipments of feed and livestock. They feared to incur some liability for discrimination, against which they had been specially protected in 1934 by a provision in the Drought Relief Appropriation Act. However, they made piecemeal concessions. In the most seriously affected areas carriers quoted emergency rates on hay amounting to two-thirds of the normal rates. On coarse roughages they quoted 50 percent of the usual hay rates. On coarse grains and feeds and on feed ingredients they accepted shipments at two-thirds of the normal rates. These concessions enabled farmers to obtain feed from distant points and helped to keep local feed prices at more reasonable levels. On shipments of livestock to surplus-feed and pasture areas the railroads made a rate of 85 percent of the normal rate, with the privilege of returning the cattle on a 15-percent basis.

Comparison With 1935 Feed Supply

The production of feed grains as estimated on September 1, 1936, was approximately 42 percent below the average for the 5 years, 1928 to 1932. But the number of livestock on farms was slightly less than during the 1928–32 period. In consequence, the production of feed grains per grain-consuming animal unit was only about 38 percent below the 1928–32 level. In terms of feed-grain production per animal unit, the output was about the same as that of 1934. The 1936 drought came later than that of 1934 and covered a smaller portion of the range and pasture areas of the West. Early hay production was not so seriously affected. Hay production per hay-consuming animal was only about 14 percent below the 1928–32 average, as compared with 35 percent below in 1934. Because the 1934 drought became serious early in the season, Congress appropriated $525,000,000 for drought-relief activities. This year's drought did not become serious over large areas until late in June. No special appropriation for meeting it had been provided. Federal and State agencies modified their programs, however, in such a way as to provide substantial assistance to farmers in the drought areas.

LONG-TERM POLICIES FOR DROUGHT AREAS

Looking toward the development of a long-term program calculated to render future droughts less disastrous in the Great Plains region, a committee appointed by Executive order visited the region, conferred with farmers and public officials in the areas most seriously affected, and drew up a series of recommendations. The committee utilized the experience of numerous Federal and State agencies, many of which had dealt for many years with the problems of the semiarid lands. These agencies placed a mass of material at the committee's disposal, and the conclusions reached were in large part the result of studies and experiments begun long ago. In thus bringing to a focus the best available knowledge on the subject the committee accomplished a work of outstanding public importance and laid a foundation for an effective remedial policy. The com-

mittee's findings, in which I heartily concur, may usefully be summarized in this report.

Analyzing the causes of the present disaster, the committee assigned primary importance to the attempt which has been made for several decades to impose on the Great Plains a system of agriculture not adapted to the region. Methods suited on the whole only to a humid region were introduced into a semiarid region. This was largely the outcome of a mistaken public policy. The Federal homestead law, for example, kept land allotments low and required that a portion of each allotment should be plowed. This policy, the committee said, caused immeasurable harm. On the western Plains it was both a stimulus to overcultivation and a condemnation of the cultivators to poverty.

Efforts to cure the trouble by enlarging the allowable individual holding did not work. In western North Dakota and Montana tracts two or three times the size of those actually granted would have been necessary to support farm families adequately. As the ranges were enclosed, feed crops were grown by intensive cultivation and the ranges were overstocked. Overcropping, overgrazing, and improper farm methods generally made the soil loose and unstable, promoted soil blowing and washing, lowered the ground-water level, and rendered the whole area extremely vulnerable to periodic droughts. The settlers themselves could not avoid these mistakes. They lacked both the knowledge and the incentive to do so and were the victims of a mistaken national policy.

Settlement of the western Plains began, the committee observes, at the end of what appears to have been a 40-year dry period. It proceeded during a wet period which now seems to be terminated. Droughts in the region during the latter part of the nineteenth century and the early years of the twentieth century were brief and infrequent. Farmers regarded them as exceptional and did not change their farming methods. Weather records indicate, however, that a long dry period preceded the settlement of the Great Plains and that we may now be in the midst of another prolonged dry period. This may have its wet years but may keep the average rainfall for a period below the long-time average.

It is impossible to make a confident forecast. But whether the present drought condition be brief or prolonged, the problems of the Great Plains region will remain essentially the same. Continued farming and ranching by the existing methods will cause continued trouble under any climatic conditions that are likely to prevail. The problem is not the product of a single drought or even of a series of bad years. It is the outgrowth of a mistaken policy pursued for decades.

The Critical Area

The Great Plains comprise an area stretching from west central Texas to the border of Canada. On the west the Rocky Mountains are the border. On the east the region is irregularly delimited near the one-hundredth meridian, where formerly the short-grass country merged into the tall-grass or prairie country. In the critical area are the Texas Panhandle, the Oklahoma Panhandle, northeastern New

138904°—37-

Mexico, and all the northern portion of the Plains. Annual rainfall is low throughout the entire region. There are short, intense storms, wide fluctuations of temperature, and strong prevailing winds. Frost and snow make wind erosion a less serious danger in the north than in the south; but soil blowing and soil depletion occur throughout the region, particularly in areas of excessive plowing.

Millions of acres of the natural cover, the buffalo grass and grama grass, have been destroyed in the Great Plains and the soil made loose by continued cultivation, decay of grass roots, and reduction of the humus supply. This destructive process has been accelerated since the World War. Eight States lying partly within the region had 103,200,000 acres of harvested crops in 1929, as compared with 87,800,000 in 1919 and 12,200,000 in 1879. How wrong this plow-up program was can be inferred from the records made under the Homestead Act. Only 60 percent of the entries were perfected prior to 1916. Since then only 45 percent of the entries have been perfected.

The results of attempts at the intensive cultivation of the Great Plains over a tremendous aggregate area have been bankruptcy, tax delinquency, absentee ownership, and excessive tenancy. In 1935 the percentage of tenant farmers in eight Great Plains States was 41.1, as compared with 15.5 in 1880. Many farms have been abandoned. Many residents moved out of the Great Plains between 1930 and 1935. The "suitcase farmer", of whom there were too many, visited his land only a few weeks each year for planting and harvesting. In drought years he abandoned his crop. He never made permanent farm improvements. Community services declined. The problem is not simply one of short-term relief but of long-term readjustment and reorganization.

Primarily, it is necessary to check overcropping and overgrazing, so that both soil and water may be conserved, and this end cannot be attained exclusively by individual action. Yet the committee's proposals do not strike at the independence of the individual farmer. On the contrary, the action recommended should restore an independence that has largely been lost. New public policies, designed to correct the existing mistaken policies, will stabilize the economy of the region and increase its power to maintain independent farm families. The fundamental requirement is to bring farming and livestock-raising methods into conformity with the natural conditions.

In many measures the Federal Government should take the initiative, particularly in leadership and guidance. Federal participation may be necessary also in the construction or financing of public works. Past Federal policy encouraged the misuse of the Great Plains. Present Federal policy should encourage the correct use. In emphasizing this principle the committee states that there need not be any conflict of jurisdiction between Federal agencies on the one hand and State and local agencies on the other. It believes that joint cooperative effort will prove workable, and more effective than any other method. Needless to say, the action taken should be continuous over a long period, with Federal and State agencies undertaking the functions they are best able to perform.

Combination of Measures Necessary

Efforts to develop a Great Plains economy capable of withstanding recurrent drought will require various measures involving Federal, State, and local cooperation. The basic aim should be to arrest excessive soil erosion and to conserve water. Public grants and subsidies should be harmonized with a plan calculated ultimately to do away with the need for such aids.

Soil and water conservation will require engineering, good agronomy, changes in tillage practices, financing, and public education. On cultivated land it will be necessary to promote contour plowing, listing, terracing, strip cropping, and other soil-conserving practices. Dams may be of use in checking water erosion and in holding water for use in dry periods. Reservoirs and wells should be developed. Small irrigation systems for groups of families will be found useful. In some areas large irrigation projects may be needed. Certain submarginal lands should be permanently withdrawn from farming.

Measures of this kind, however, can merely improve the conditions and practices on individual farms. They cannot effect the basic changes necessary in the whole land-use pattern. Therefore the committee recommended that public acquisition of lands should be continued on the basis of selecting those areas less suited to cultivation and grazing. Extension of the grazing range could be brought about in certain areas by bringing some arable farm land under public ownership. Abandoned farms or tax-delinquent land could sometimes be acquired. Land in some areas, it proposed, should be leased or optioned, with a stipulation that the users shall carry on an approved program of restoration to grass or forest.

Public land buying and regulated grazing, however, will not be fully efficacious if private owners may still use their holdings in a manner destructive to neighboring property as well as to their own. Therefore the committee suggests that the possibility of restraining wrong land uses should be explored within legal and constitutional limits.

In some areas cooperative grazing districts are attempting to prevent the overgrazing of their lands; and this policy the committee warmly endorsed. Each thing done, it declared, should be part of a coordinated project covering the entire region. As an aid to the cooperative control of grazing, it suggested that public land buying in some areas would help to block out desirable ranges. Such a project could be set going without arbitrary action by any public agency, and it could be carried out democratically by using existing facilities for ascertaining local interests and wishes. The pooling of scientific knowledge in a well-conceived educational campaign would be indispensable.

Research should be undertaken to determine how many people the region can properly support. With that determined, the problems of migration and relocation would be simplified. While discouraging aimless migration, the committee believes that in some areas a regrouping of the population would be beneficial. It is impossible, as yet, to determine whether or not the region can adequately support its present population. A shift from cropping to grazing might reduce the population in some localities but at the same time increase

the real wealth of the region as a whole. Ultimately, the change would provide additional income. The fundamental purpose is not to depopulate the region, but to make it permanently habitable. Any other aim would be a confession of failure. In the long run the Great Plains will support more people on a higher standard of living if its agriculture is regulated intelligently than it can possibly support if present tendencies run their course.

In some localities farm holdings should generally be larger than those now prevailing. Such necessary increase in the size of farms would require governmental assistance. State and county governments may expedite the consolidation of small units by making available to grazing and other cooperative agencies certain tax-delinquent lands, which will not again be cultivated by their nominal owners. The aim should be to develop holdings large enough to support farm families in independence and comfort.

It is proposed that the possibilities of rural zoning be explained as a means of preventing the sporadic settlement and breaking up of lands better adapted to range use than to arable farming.

The committee recommends the use of public credit to enable competent tenants to purchase and operate their own farms. Tenancy, it says, promotes soil mining and does not suit the Great Plains. Also, the committee recommends the study of crop insurance and of ways and means to promote the transfer of certain croplands to grass farming. It urges public guidance in resettlement, and investigations to determine what new Federal legislation, if any, will be necessary. Essentially the committee finds that, while present methods in the Great Plains do not promise success, methods suited to the region can be developed through Federal, State, and local cooperation.

Crop Insurance

In the farmer's life luck and chance are important factors. Each crop planted is a speculative venture. Unfavorable weather conditions, floods, insects, or disease may cause a partial or a complete failure of his crop. Studies of total farm income for all farmers do not tell the whole truth. Increases in prices in years of low production enhance the income of farmers who have a good crop, but benefit very little those whose crop fails. The distress due to widespread crop failure and the resulting necessary expense for relief suggest the need of some form of crop insurance.

The programs of the Agricultural Adjustment Administration contained a measure of crop insurance. The benefit payments were the only income of many farmers after the drought of 1934 had destroyed their crops. Undoubtedly the soil-conservation payments of 1936 will likewise serve as crop insurance in drought areas. Crop insurance resulted as a byproduct of the adjustment program in connection with the administration of the Bankhead Cotton Control Act. In 1934 many farmers in the western part of the Cotton Belt produced less cotton than their allotment of tax-exemption certificates covered. Through the operations of a pool set up to make transfers, they were able to sell their surplus certificates to farmers elsewhere who had produced cotton in excess of their allotments. Sale of their certificates

enabled farmers who had suffered a partial or complete crop failure to recoup part of their losses.

The principle of crop insurance merits a prominent place in any broad plan for a national farm policy. Insurance viewed from the standpoint of the individual appears primarily as a contract for the indemnification of losses. Viewed from the standpoint of the whole group, however, it appears rather as an averaging of losses. The insured individual pays the average loss instead of taking the chances of suffering a larger loss. Insurance is a social device by which "the loss lighteth lightly upon the many rather than heavily on the few."

Crop insurance is a means by which systematic contributions by farmers, made in proportion to the risk to their crops, create a reserve out of which agriculture can finance its own relief from crop disaster. It does not prevent disaster, but it does provide that the full weight shall not fall on a few.

Crop insurance differs in some respects from other types of insurance. It insures against the loss, not of an existing value, but of a prospective value. In fire insurance loss can readily be measured, because the value of the property is known or can be estimated. But if a crop fails, what is the loss? Is it the difference between the actual production and a bumper crop; between the actual production and an average crop; or between the actual production and the investment in the crop?

Many have questioned whether it is sound policy to insure prospective profits and have advocated insuring only the investment in the crop. But the investment in the crop is difficult to determine. Much of it represents the farmer's labor and other items that must be evaluated. Little of it represents a cash outlay that can be measured accurately. It seems better to insure only a certain proportion of the average yield. That is much simpler. If only a reasonable percentage of the average yield is insured, the plan does not include the insurance of prospective profits.

Requirements of Crop Insurance

Crop insurance should have a large element of saving. That is, it should involve not merely a horizontal averaging of losses for each year but also a vertical averaging of losses over a period of years. Losses in certain years may be so widespread that accumulations from more successful years are necessary to help carry the burden. This is very important. Hence the rates for crop insurance should be based on the average losses over a long period or over a shorter period that was worse than the average for most short periods of years. The successful operation of a plan for a few average years does not prove that it could successfully meet widespread disaster for several years. Substantial reserves should be built up in good years.

All-risk crop insurance is not available to the farmer today. Insurance companies have made several attempts to insure the crop of wheat and other grains. In 1917 such an attempt in the spring-wheat area failed partly because of drought and partly because insurance was written after it became apparent that there would be a short crop. In 1920 another attempt failed largely because it included price insurance, and prices fell off sharply. Still another attempt in 1931 and

1932 failed because of a sharp drop in prices. But hail insurance, a specialized type, has proved successful.

Insurance has quite frequently been written on fruit and vegetable crops, particularly against frost and freeze hazards. Such insurance has sometimes been taken out only to protect the creditor. There is little being written today, most of the companies having withdrawn from the field. The experience was not always successful. The hazards were so great that a single company could not afford to carry the risk and reinsurance on such business was difficult to arrange. The large uncertain hazard for a single company necessitated high rates.

If crop insurance is to be made generally available to the farmer, probably the Government must assist. The Government is better able than private enterprise to carry out the venture on a scale large enough to reduce the impact of heavy losses in certain areas. Insurance, where extensive public protection is at stake, is not new for the Federal Government. We have insurance of bank deposits, insurance of loans for financing the construction and repair of houses, and life insurance for veterans. Also, we have unemployment insurance and a system akin to insurance for providing old-age annuities. Crop insurance would provide the farmer with a measure of social security comparable in some ways to the unemployment insurance and old-age retirement from which he is excluded under the Social Security Act.

Crop insurance, to be successful, should have an actuarial basis. There is little crop-insurance experience to study and reliance must be placed on the loss experience of farmers in general, with proper allowances for an adverse selection of risks. This Department is studying the problem with data for individual farms gathered incident to the adjustment programs of the Agricultural Adjustment Administration. These data cover a 5- to 6-year period which included several drought years. They are supplemented by estimated average-yield data for a long period. The estimates of cost derived therefrom should be conservative. The study emphasizes a type of insurance in which the coverage would be a certain fraction of the yield on the insured farm. Such a plan would not put a premium on the farming of poor land or on poor farming practices.

Differences among areas and counties are being studied, because rates would have to vary. Rates based on average costs over a wide area would attract only those who were favored by these rates. They would bring into the insurance group only farmers with risks greater than the average. In that event the losses would exceed the premiums collected. As far as possible, premium rates and insurance coverage should be so adjusted that each type of farmer and each type of farm would bear its own cost. Over a period sufficiently long, each farm should bear its own cost.

Crop insurance must not benefit the shiftless at the expense of the thrifty, and the poor land at the expense of the good. In large measure the insurance coverage and the premium rate should be based on the experience of the individual farm. The insurance coverage for an individual farm should probably be a given percentage of the average yield for that farm. The premium rate should prob-

ably, in a measure, be based on the average crop losses of that farm. The data acquired for individual farms in the agricultural-adjustment program might provide a starting point.

Principle of the Ever-Normal Granary

Crop insurance would be an attempt to solve the problem of short crops. But bumper crops have not been an unmitigated blessing to the farmer. Frequently a large crop sells for less than a medium or a small crop. Both problems arise from wide variations in production, the one being the counterpart of the other. Perhaps a single solution could be worked out for both problems. Some system that would tend to level off the amount that individual farmers could and would place on the market in various years would tend to solve both problems.

In line with this thought the Department, in its studies of the costs of crop insurance, has given some consideration to the possibilities of the option of paying for the insurance "in kind", out of the production of years of surplus. This should make the burden of the insurance premiums lighter and easier to bear. In the sample studies that have been made the surplus production was calculated for each farm, the surplus production per acre being considered as the excess of the actual yield over the average yield. Only a fraction of that surplus would be needed to pay for insuring the yields up to 75 percent of the average yield for each insured farm. In fact, for the 6-year period 1930–35 only from one-third to two-thirds of the surplus production would be necessary to meet the net cost of such insurance.

The plan, involving payments in kind and payment of premiums only in years of surplus, would really become the ever-normal granary plan with crop-insurance requirements serving as an automatic regulator. In years of surplus a part of the crop would be drawn off the market and put into storage—the amount so drawn off being regulated by the predetermined insurance rates based on actuarial calculations. In years of crop failures the stored commodities would be released, the amount being automatically determined by the amount of indemnities necessary as defined by the insurance contracts. Since the plan would operate automatically, with the commodities being released from storage only in case of crop failure, the commodities in storage would not be a potential supply on the market tending to depress the price.

During surplus years the removal of the excess commodities from the market would tend to support the price. The part of the crop not used for insurance premiums would still be more than the farmer's average production, and with a supported price the income from the crop should be reduced but little, if at all. The release of commodities from storage in years of crop failure would tend to hold down the price, but farmers without a crop do not benefit from high prices. Under this plan the farmers who lost their crop would be indemnified, while the farmers who produced a crop would get at least average prices.

Furthermore, as a form of price stabilization this plan would require no funds to buy up the commodity. The participating farmers would provide the capital in the form of premium payment in kind.

Any Plan Should Be Optional

While the above plan for crop insurance has many excellent features, it would present many problems. The Department is committed to no single plan. It is interested in all possible angles of the problem and in various possible plans. Certain plans may be suited to some areas, and other plans to other areas. Any plan adopted should be voluntary and optional with the farmer.

Crop insurance is needed most in the single-crop areas. In regions of diversified farming the loss of a single crop is less calamitous. But though diversification is a form of self-insurance, it does not adequately offset losses from extensive droughts, floods, and infestations. Another form of self-insurance is the accumulation of reserves of feed and supplies and the accumulation of savings in some form of investment. But this method, too, needs often to be supplemented.

Farmers have learned much in recent years about handling their local farm problems. Their experience under the A. A. A. should provide a base for the local administration of an insurance program. But if crop insurance is tried, it should be as an experiment and should be confined at first to one or two crops—wheat and possibly corn or cotton. It should be limited in the beginning to areas where there is a real need and a real demand. It should not be considered a complete protective program in itself, but should be part of a larger unified program involving soil conservation, retirement from farm uses of land unsuited to agriculture, judicious commodity loans, and the ever-normal granary.

COTTON

In some respects the cotton situation is better now than it has been for several years. This year's crop of 12,400,000 bales (November estimate) is larger than that of 1934 to 1935, but the carry-over of American cotton is the smallest since 1930, and the world supply of American cotton is the smallest in 12 years. There is no shortage of American cotton. On the contrary the supply is more than ample, but in comparison with the situation in recent years the present supply-and-demand relationship is not so unfavorable to the producer. In fact, returns to domestic growers promise to exceed those received for any crop since 1929.

Since August 1932 the world carry-over of American cotton has been reduced from 13,000,000 to 7,000,000 bales. Though still somewhat larger than an average carry-over, this quantity is 2,000,000 bales below the carry-over in August 1935 and is the smallest in 6 years. The total world supply of American cotton this season will be about ¼ million bales less than in the previous season, despite the increase in the 1936 crop.

Income to farmers for cotton marketed during the present crop year will probably be the largest since 1929–30, though about 30 percent below the average for the period 1919 to 1929. Among the causes of the improvement are of course recovery of business at home and abroad, changes in the supply position, and the reciprocal trade agreements program which the Government has instituted. This program benefits cotton exporters by enabling foreign

buyers to get dollar exchange. Part of the advance which has taken place in the price of cotton since 1933 may be attributed to dollar revaluation. Production control has been an important factor. The revaluation by itself would probably have encouraged farmers to increase their output and would have tended to counteract the influence of the monetary policy. The improvement in the cotton situation is the outgrowth of numerous factors the separate influence of which cannot be accurately measured.

Certain unfavorable aspects of the situation should be noticed. World consumption of cotton in the 1935–36 season was about 27,700,000 bales, the largest consumption on record. American cotton accounted for 12,500,000 bales, as compared with 11,300,000 bales the previous season. Though American cotton represented a slightly larger proportion of the consumption in 1935–36 than it did in 1934–35, it was materially below the average for the decade ended 1933. Mill consumption of foreign cotton, on the other hand, increased to a new high level and was above the 10-year average and above the consumption of American.

Numerous factors contributed to this shift in the relative consumption of American and foreign cotton, some of them of long standing. The production of cotton in other countries increased rapidly after the World War, side by side with an increase in our own production. Meantime trade restrictions throughout the world, among which our own tariff policy exercised a large influence, tended to handicap our cotton-export trade. Foreign countries turned as much as possible to foreign cottons, particularly when they could offer industrial commodities in exchange. They wanted to buy where they could sell, and the American tariff policy made it difficult for them to do so in the United States.

Obstacles to Cotton-Export Trade

When cotton prices and income fell to the low levels of 1932, it was evident that something had to be done to help American growers. With the aid of the Federal Government domestic producers undertook to readjust their output. The ensuing price recovery inevitably benefited foreign as well as American cotton growers, and the trend toward relatively increased production of foreign growths, which had long been in evidence, continued, although perhaps not to the extent implied in the trade press.

Obstacles quite independent of our production policy stand in the way of increased foreign consumption of American cotton: (1) The difficulty foreign consumers still have in getting dollar exchange, and so long as we bar out foreign goods this difficulty cannot greatly diminish. (2) Other countries are forging ahead in cotton production. (3) The competition of other fibers is growing. These obstacles, however, can be surmounted. Recent trends in our tariff policy are steps in the right direction. Our advantages in cotton growing are substantial, and the world demand for cotton should continue to increase. When he can do so without losing money, the American grower will respond. The Department is engaged in an extended cotton-breeding program which should play its part eventually in making the American cotton grower the most efficient in the world.

WHEAT

DESPITE the effects of the drought the total supply of wheat in the United States for the 1936–37 season is large enough for the usual domestic requirements. Supplies of hard red spring wheat and durum wheat are short, however, and imports of these types will continue. The drought reached its greatest intensity in the hard red spring and durum wheat areas. The winter-wheat crop was larger than that of 1935 and of good quality. Probably the spring-wheat mills will use a larger percentage of hard red winter wheat and Pacific Northwest wheat this year than they did last. More than the usual quantity of soft red winter wheat will probably be used in bread flour. It is expected therefore that the imports of milling wheat in 1936–37 will not exceed the 26,000,000 bushels imported in 1935–36.

The Pacific Northwest, the principal white-wheat region, again produced a surplus. In 1933–34 the disposal of its surplus was financed out of processing-tax funds. In 1935–36 exporters in the Pacific Northwest were indemnified for losses sustained on exports to the Philippine Islands, funds for which were made available from tariff revenues under section 32 of the amended Agricultural Adjustment Act. In this same year, as well as in 1936, considerable amounts of white wheat from the Pacific Northwest moved east of the Rockies, some of it going into relief channels. Ordinarily, however, wheat from the Pacific Northwest cannot compete east of the Rockies with Great Plains wheat, which normally constitutes the bulk of our supply of bread wheats. In years of average United States production the Pacific Northwest must seek a market abroad.

Since 1933 wheat prices in the United States have been high in relation to the world market price. They have ranged from 20 to 30 cents a bushel higher than they would probably have done had our production been normal. Average or above-average yields in this country next year would give an export surplus and cause an adjustment of the domestic price toward an export basis. On an acreage equal to that seeded for the 1936 crop, yields one-fourth below the average would provide enough wheat for the usual domestic utilization.

Our wheat farmers continue to expand their acreage. The area seeded for the 1936 crop was 74,500,000 acres, the largest on record with the exception of that seeded in 1919. In 1935 growers who had signed the A. A. A. wheat-adjustment contract had the right to plant 95 percent of their base acreage. But many had seeded winter wheat in the fall of 1935, before the contract was offered to them, and there was a tendency for farmers to plant larger acreages. In addition, nonsigners increased their seedings. Large acreage does not always mean large production. In years of normal growing weather, however, the existing wheat acreage in the United States will produce large export surpluses, for which satisfactory outlets do not now exist.

It is better to have a balanced acreage. With a balanced acreage less land shows a loss in drought years, and less wheat has to be sold below cost in years of normal crops. In 1936 the soil-conservation program provided payments to wheat growers for the diversion

of land from soil-depleting to soil-conserving crops. However, the list of soil-depleting crops included many crops besides wheat, and participating growers did not have to make any adjustment in their wheat acreage if they were in a position to divert other land from soil-depleting to soil-conserving uses.

Cash farm income from wheat in 1936 may be between $425,000,000 and $465,000,000, exclusive of payments to wheat farmers under the agricultural conservation program. The corresponding figure for 1935 was $353,284,000, excluding the $115,368,000 in the A. A. A. adjustment payments. Cash farm income from wheat in 1932 was only $195,860,000. Needless to say, the income from wheat this year will be very unequally distributed as a result of the drought. Growers in the States worst affected will receive comparatively little, while growers in the States not affected will make large returns. This rough estimate of wheat income rests partly on the expectation that world wheat prices in 1936–37 will be materially higher than they were in 1935–36. Several important wheat countries, as well as the United States, have below-average production this year.

Distribution Within the United States

Market outlets will have more effect on the distribution of wheat within the United States in the future than they have exercised heretofore. In the 1920's there was a good demand for wheat in the markets of the world. All that was grown was sold at prices fairly remunerative. That is no longer the case. Formerly this country exported principally hard red winter, durum, and soft white wheats; there was a sufficient market at home for all or nearly all our hard red spring and soft red wheats. Hereafter the absence of an adequate foreign demand may create new problems of internal competition.

Our high-quality hard wheat is produced in the Great Plains under changing weather conditions and with widely fluctuating yields. Other regions are not adapted to producing it. Varieties of hard red spring and hard red winter wheat are grown to some extent in the Pacific Northwest and in the Corn Belt, but the product is less desirable for milling than the wheat grown in the western Great Plains. Farmers in the soft red winter wheat region may shift from wheat to other crops, as the prices of the latter crops rise in relation to wheat prices. In the Pacific Northwest, however, the farmers have fewer alternative crops to which they may turn, and this region will continue to be a specialized wheat region. This area will continue to have a considerable surplus of the soft wheats for export.

In the Great Plains the bread wheats will be the mainstay. Part of the area plowed during the 1920's is better suited to ranching. Elsewhere, however, the Great Plains will continue to produce wheat, despite the prevailing climatic and other hazards, because the wheat grown there has exceptional value for milling and because wheat in large areas of the Great Plains had a marked comparative advantage over other crops. Measures should be taken to stabilize the income from wheat in this region so that the Nation may have a reasonably dependable supply of bread wheat.

LIVESTOCK AND FEEDS

Recovery in livestock production was under way last year following the 1934 drought, but this year's drought checked it. On January 1, 1936, the number of grain-consuming animal units on farms was somewhat greater than it had been a year earlier, when it was the lowest since early in the present century. On the other hand, the number of hay-consuming animal units on farms was slightly lower than a year ago, though above the 10-year (1925–34) average. In January 1937 the number of both grain- and hay-consuming animal units on farms may be as low as, or even lower than it was, in January 1935. There was relatively heavy marketing of cattle and hogs in the fall of 1936, and close culling of dairy herds and poultry flocks. Moreover, the fall pig crop was smaller than that of 1935.

Total feed-grain production in 1936 was larger than that of 1934. There was a larger supply of hay and roughage. In consequence the feed situation following the 1936 drought will be easier than was that following the 1934 drought. Farmers will be better able to winter their cattle, sheep, and work stock. But supplies of pork and the better grades of beef will be reduced next year. They may be almost as small as in 1935.

In 1936, for the third consecutive year, the demand for meats improved. Though lower than in the 5-year period prior to 1931, it was about equal in the first half of 1936 to what it was in the first half of 1931. Consumers spent for meat in this period about 12 percent more than in the corresponding period of 1935. They spent about 50 percent more than in the first half of 1933. The improvement, of course, reflected general economic recovery. There was a marked increase in both the total live and dressed weights of animals slaughtered under Federal inspection; the second half of the year will probably record a further increase. Total slaughter for the year will be much larger than it was in 1935, though less than the average for the 5-year period 1930–34. In 1937, however, both the number and weight of the animals slaughtered will decrease. It is not probable that total yearly slaughter will again be equal to the average of 1930–34 before 1940. The feed situation will affect the trend of hog numbers more than the trend of any other species of livestock.

Indications on September 1 were that the 1936 corn crop would be slightly smaller than that in 1934 and the smallest in 55 years. On the other hand, the production of oats, barley, and grain sorghums was large enough to give a combined production of feed grains of approximately 58,000,000 tons, as compared with 54,000,000 tons in 1934 and 93,000,000 tons in 1935. Corn prices will be relatively higher during most of 1937, and hog production will be sharply curtailed. Though the number of hogs available for slaughter in the 1936–37 marketing year will be larger than in 1935–36, hog production for the calendar year 1937 will be smaller than in 1936. Hog prices for the marketing year beginning October 1 will probably average about the same as they did in 1935–36.

Despite the drought, the income to corn and hog producers was materially larger than that of 3 years ago. During the winter of 1932–33 the farm price of hogs fell below $3 per 100 pounds, the

lowest level in more than 50 years. Income from the sale of hogs in 1932 amounted to only about $440,000,000, as compared with an income of about a billion dollars for a number of years prior to 1930. In 1936 the income from the sale of hogs was about $840,000,000, and the farm price averaged $8.80 per 100 pounds. This sharp increase in prices and income from the depression level in 1932 occurred despite the absence of any material improvement in foreign demand for hog products. The foreign market for United States hog products retains only a fraction of its former proportions. Import restrictions in foreign countries and a marked revival in European hog production, which began effectively to curtail United States exports of hog products a number of years prior to 1932, continue to be the principal causes of greatly reduced exports. Exports of pork and lard fell from about 2,000,000,000 pounds in the early post-war years, to a little more than one-third as much in 1932, and since have remained at approximately that level.

Uneven Distribution of Corn-Hog Income

Although the income of farmers in the Corn Belt States was much greater in 1936 than in recent years, its distribution was very abnormal. In the States hardest hit by drought, such as South Dakota, Nebraska, and Missouri, the supply of corn, hogs, and other farm products for sale was very small, and even though prices were very favorable the income of farmers was small as compared with the income in the other Corn Belt States, where the effects of the drought were not nearly so great. The uneven effects of the drought were reflected in uneven distribution of farm income. In such States as Nebraska and South Dakota, where farmers had not recovered from the effects of the 1934 drought and where very little was obtained from the sale of cash crops in 1936, the payments received for participation in the 1936 agricultural-conservation program constituted a substantial proportion of their total income for the year. As was the case in 1934, payments for participation in the agricultural program received by farmers in the drought areas were in the nature of partial insurance against reduction in incomes resulting from drought.

Cattle

The general cattle situation was less influenced by drought in 1936 than in 1934. In parts of the northern Great Plains, however, heavy liquidation of cattle was necessary. Beef cattle numbers at the beginning of 1937 will probably be smaller than they were at the beginning of 1936, though still above the average for the 10 years 1925–34. In January 1936 the total number of beef cattle, including calves on farms, was approximately 32,300,000 head, as compared with 36,100,000 head in 1934, when beef-cattle production was nearing a peak in the typical production cycle. Because of the reduced level of hog supplies, in competition for the consumers' meat dollar, the cattle industry is now in a rather favorable position, and for the next few years the trend in cattle numbers will probably be upward. In the first half of 1936 the average price paid by packers for all cattle slaughtered under Federal inspection was $6.60 per 100 pounds, or slightly lower than that in the first half of 1935.

Sheep

Sheep and lamb producers fared comparatively well during the last months of 1935 and most of 1936. Prices were above the levels of recent years, though slaughter was relatively high. Sheep and lamb production in 1936 was less affected by drought than in 1934. The feed position is better for sheep at present than for hogs and cattle, though in the Corn Belt many lamb-feeding areas have short feed supplies.

The 1936 lamb crop was about 9 percent larger than that of 1935 and only slightly smaller than the record lamb crop of 1931. Further expansion in the western sheep industry may be checked, however, by grazing-control measures instituted for the public domain in western areas under the Taylor Act.

The production of shorn wool in 1936 was slightly smaller than in 1935 and total supplies of wool on hand in this country at the end of June were smaller than a year earlier. Wool prices in 1936 rose to the highest levels since 1929. Relatively high wool consumption in Europe and a relatively low foreign wool supply strengthened both foreign and domestic prices.

In the United States, however, the consumption of wool during the first 7 months of 1936 was somewhat below that of the first half of 1935, though above the corresponding monthly average for the last 10 years.

DAIRYING

Increased business activity and fuller employment caused an improvement in the demand for dairy products, while the drought curtailed production. Prices for fluid milk rose and also prices for manufactured dairy products. Butter prices were 100 percent above the low point of the depression. Consumption of fluid milk and cream, which declined in the early years of the depression, turned upward in 1935 and continued upward in 1936. Markets that had been burdened with surpluses faced temporary shortages. The consumption of ice cream, and also of evaporated milk and cheese, increased. With prospects good for further improvement in business activity and employment, the dairy industry expected continued improvement in the demand for its products.

It seems probable that the drought, like that of 1934, will have proportionately less net effect on dairy production than on the output of other livestock products. In 1934–35 total milk production per capita was only about 5 percent below the peak of 1931. Dairy production in 1936–37 will probably be only from 5 to 7 percent less than it would have been had the weather of 1936 been normal. However, the effects of the drought will be felt in 1937–38 in a reduction in the number of cows on farms and in the number of heifers raised. It is expected that the number on farms will decline in 1937 to a relatively low level, owing to the heavy reduction caused by the drought in the supply of feed.

Between January 1, 1927, and January 1, 1934, the number of milk cows on farms increased 21 percent. This was much more than the proportionate increase in the human population. In fact, in 1934 the number of cows per capita was the highest in 35 years. From this point the drought of 1934 caused a decline, which continued in

1935. By January 1, 1936, the number of milk cows per capita was about equal to the average for the 30-year period 1900–1929.

The trade agreement with Canada that went in effect on January 1, 1936, contains provisions affecting the dairy industry. It provides for a reduction of the import duty on cream from 56.6 cents a gallon to 35 cents a gallon on not more than 1,500,000 gallons annually, and also for a reduction in the duty on Cheddar cheese in original loaves from 7 cents a pound, with a minimum of 35 percent ad valorem, to 5 cents a pound, with a minimum of 25 percent ad valorem. However, the reduced rate on cream is 5 cents a gallon higher than the rate established by Presidential proclamation effective June 13, 1929; it is the highest rate on cream the United States has ever had, with the exception of the rate established in the Tariff Act of 1930. The reduction in the rate on Cheddar cheese brings it down to the level that was in effect from September 1922 to June 1930.

In the first 6 months of the agreement the importation of cream amounted to only 6,233 gallons. The total imports of cheese amounted to 24,400,000 pounds—about the same as the relatively low imports of the first half of 1935. Canada contributed about a sixth of the total. In judging the effects of the reduced tariff rate on cheese it should be remembered that less than 6 percent of the milk produced in the United States goes into the production of cheese and also that our imports of Cheddar cheese are a small proportion of our total cheese production. The reductions in the tariff rates on cream and cheese will have little or no effect on the level of dairy prices.

TOBACCO

THE 1936 tobacco crop, on the basis of September 1 indications, was the smallest since 1921 with the exception of the crops of 1932 and 1934. It amounted to 1,142,900,000 pounds, or 11.9 percent below the production of 1935 and 16.2 percent below the average for the 7-year period, 1923–29. Drought conditions were mainly responsible for the reduction. In many tobacco areas the acreage planted exceeded that of 1935. Only the cigar binder, the cigar wrapper, and the Georgia-Florida flue-cured types showed an increase in production. The production of all other types was much below that of last year, and the quality in many of the drought areas was impaired.

However, the stocks of domestic tobacco (farm-sales weight) held by dealers and manufacturers, though 1.5 percent below those of 1935–36, were still 24.6 percent above the 7-year average, 1923–24 to 1929–30. The available supply is estimated at more than 200 million pounds above normal requirements for domestic consumption and exports and for carry-over at the end of the year. The consumption of nearly all tobacco products increased in 1936. In the first 7 months of the year cigarette consumption reached an all-time record for that period. Indications are that the increase will continue. Tobacco consumption per capita does not seem to be much affected by changes in price, but it increases with business recovery and employment. Our tobacco exports increased. Flue-cured tobacco, the predominant export type, represents about 70 percent of the total

exports; and the exports of flue-cured tobacco in the last fiscal year were 32 percent above those of the preceding fiscal year, though 2.3 percent below those of 1933–34. Exports of Maryland tobacco increased in 1936, while exports of other types declined.

Should the weighted average price for all types of tobacco not fall below the August prices for the Georgia and Florida flue-cured type and for the South Carolina flue-cured, the income to farmers from the sale of leaf would be about equal to what it was in 1935.

FRUITS AND VEGETABLES

Fruit and vegetable production, according to the September estimate, was about 11 percent less than in 1935, 9 percent less than in 1934, and about 6 percent below the average for the period 1928–32. Truck crops decreased 13 percent, all fruits 9 percent, potatoes 20 percent, and sweetpotatoes 19 percent. On the other hand, truck crops for fresh market shipment were about 5 percent larger than in 1935. Reduced plantings and the drought were the chief causes of the drop in the production of truck crops for canning, of potatoes, and of sweetpotatoes. Fruit crops suffered comparatively little from the drought, but a severe late spring frost damaged apples, peaches, cherries, and grapes. Favorable growing conditions later failed to offset the damage, though citrus production was larger than in the previous year.

Acreage planted to all truck crops for canning was about 4 percent less than in 1935, but slightly larger than the harvested acreage in 1935 or in any previous year. Abandonment was substantial, owing to the drought. Drought and heat combined reduced the yields, which for all canning crops were about 10 percent below those of the previous year, and, in fact, were the lowest on record. Drought damage was severe to sweet corn, snap beans, and green peas. The total supply of canned vegetables will be about 10 percent below the figure for 1935, but 19 percent above 1934. Production of vegetables for fresh market shipment was higher than in 1935 owing to an increase in the acreage. Yields were generally about the same, though dry weather injured late cabbage. On the whole, the supply of fresh vegetables was ample. Income to the growers, moreover, was higher than for several years.

Potato production was estimated at only 312,000,000 bushels, as compared with 388,000,000 bushels in 1935. The acreage, however, was 10 percent less, and drought damage was severe except in the far West. For the country as a whole the indicated yield was only 97 bushels per acre, as compared with 109.2 bushels in 1935 and a 10-year (1923–32) average of 112.7 bushels. Sweetpotato production, though small in comparison with that of 1935, was above the 5-year (1928–32) average.

In fruit production the 9-percent decline was largely in apples, peaches, cherries, and grapes. The apple crop was 35 percent less than in 1935 and was the smallest since 1921. Production of pears, apricots, fresh plums, prunes, strawberries, cranberries, and citrus was larger than in 1935. Citrus production may be one-sixth larger than last year, while production of all fruits combined, except apples and citrus, may be 12 percent smaller.

POULTRY

WITH poultry flocks not fully recovered from the reductions caused by the 1934 drought, the drought of 1936 is causing reductions again. However, hatchings increased greatly last spring. There will probably be as many laying birds in farm flocks at the beginning of 1937 as there were a year before.

One important effect of the drought will be observed in the relation of egg prices to feed prices. When feed prices rise more than egg prices, sales of laying birds tend to be greater, production per bird declines, and in the spring some reduction in hatching occurs. The hatch of 1935 was reduced following the drought of 1934 because of an unfavorable relationship between feed prices and egg prices. Hatchings in 1937 may decline similarly.

On the whole, prices of eggs and poultry in the first part of 1936 have been favorable to the producer. Poultry prices, however, are now declining. After the drought liquidation ceases they may resume the upward trend of the last 3 years. Egg prices in early 1937, if they follow the course set after the drought of 1934, may continue the present rising tendency.

AGRICULTURAL CREDIT

FARM-CREDIT conditions have improved materially during the last year or so, largely as a result of improvement in farm incomes and a large amount of refinancing for long terms at low rates of interest. In 1935 the demand for farm-mortgage loans declined sharply but remained more nearly steady in the first half of 1936. Private lenders began to return to the farm-loan field; and borrowers had the further advantage of continued low interest rates.

The character of the 1936 mortgage financing, moreover, was very different from that for the last 3 or 4 years. Loan applications to an increasing degree were from farmers who were in no particular emergency. An increasing number of the applications received by Farm Credit Administration agencies were made by young farmers and tenants. The increased prices of farm commodities were encouraging them to try to become farm owners. A large proportion of the other applications were made by farmers interested mainly in refinancing their debts for a long term of years in order to take advantage of the existing low interest rates.

The passing of emergency financing among farmers with a reasonable amount of collateral for farm-mortgage credit is indicated by the decline in the number of applications for loans from the Federal land banks and the Land Bank Commissioner, and by the reentry of private lending agencies into the farm-mortgage field. Applications for land-bank and Commissioner loans declined from 20,000 a week at the peak in 1933 to fewer than 3,000 a week in the summer of 1935 and to an average of 1,620 a week by May 1936. Private lending agencies that were estimated to be doing only about 23 percent of the farm-mortgage business in the first quarter of 1934 and 49 percent during the first quarter of 1935 were doing approximately 70 percent of the business by the middle of 1936.

During the first half of 1936 new loans of the Federal land banks were about offset by repayments and liquidation of loans as their

138904°—37——5

loans outstanding remained about steady. Commissioner loans outstanding increased slightly. Loans made by other leading lending agencies did not quite offset repayments and liquidation as their loans outstanding continued to decrease, but at a reduced rate. Furthermore, there was some evidence in farm-mortgage recordings that farm-mortgage loans made by individuals were on the increase. Some debt distress persisted, however, in areas that had suffered partial crop failures for several years, and among farmers whose debt charges reflected previously excessive farm valuations. In spite of this, the general situation had improved to the extent that Commissioner loans, which in amount are about 63 percent second-mortgage loans, were decreasing at a more rapid rate than were the land-bank loans made during the first half of 1936.

The principal backset to a more rapid improvement of the farm-credit situation came when drought developed again this year. As a result, there was an increased demand for loans for relief and rehabilitation by midyear.

Farm-Mortgage Debt

It is unusually difficult just now to estimate the amount of the total farm-mortgage debt in the United States because so much refinancing has been done recently. Adequate statistics are not available to show the net changes produced by the delinquencies, the foreclosures, the compositions, the extensions, and the charge-offs of recent years. The last official estimate placed the amount at $8,000,000,000 as of January 1, 1934. There are no precise data on all the changes that have taken place since then, but indications are that through foreclosures and other means the total has been brought down somewhat from the 1934 figure. Needless to say, the amount of the farm debt does not by itself indicate the financial position of the farmers. Whether or not it is burdensome depends on the size of the debt relative to the farm income out of which principal and interest payments can be made.

Licensed member banks of the Federal Reserve System held farm-mortgage loans amounting to $253,000,000 in the first quarter of 1936, as compared with $263,000,000 in the first quarter of 1935. Farm-mortgage loans held by agencies of the Farm Credit Administration totaled $2,869,089,100 in January 1936, as compared with $2,586,206,691 in January 1935. These figures, however, do not indicate the whole trend, as financing through other agencies is quite important, though details are not available.

Farm borrowing for current production increased during the past year. Agricultural prices were at the highest level since 1930, and some expansion took place in farm acreage and livestock breeding. Many country banks increased their loans to farmers for current production, though frequently their total loans showed little change. Lending by the production-credit associations of the Farm Credit Administration increased. In May 1936 the outstanding loans of these production-credit associations totaled $135,467,214, as compared with $101,269,485 in May 1935. It is characteristic of the early phases of agricultural revival for current production loans to increase more rapidly than mortgage financing.

Federal credit agencies during the year aided farmers through low interest rates. Interest rates on outstanding Federal land-bank loans, which had been temporarily reduced in 1935 to 3½ percent, were continued by legislation on that basis for the period ending June 30, 1937. On new mortgage loans the Federal land banks continued to charge 4 percent per annum. Other financing agencies offered low interest rates likewise, and the first half of 1936 saw some increase in farm-mortgage lending. Feed and seed loans made by the Federal Government, new lending by commercial banks, and loans from the production-credit associations helped farmers in some areas to pay cash for more of their supplies and reduced the volume of costly store credit. The Resettlement Administration enlarged its activities in handling distress cases; and by April 1936 its total loan commitments had risen to $53,793,000. After the drought the volume increased more rapidly.

The drought, of course, is complicating the farm-credit situation and delaying liquidation. Short-term credit by the Farm Credit Administration agencies and by commercial banks amounted at the end of 1934 to about $1,121,000,000. Other personal loans, store credit, credit extended by implement firms, and loans negotiated by farmers' cooperative associations made up an important additional amount. Probably the total short-term credit outstanding did not change greatly between the end of 1934 and the middle of 1936, as country-bank loans outstanding continued to decline and outstanding short-term loans by Farm Credit Administration agencies continued a steady increase.

Character of New Short-Term Credit

As in the case of farm-mortgage credit, more important than any change in the amount of short-term credit outstanding was the change in the character of the new short-term credit being extended during the first half of 1936. More of it was for productive purposes and less of it for emergency financing of old debts. As an example, total short-term credit extended by Farm Credit Administration agencies, including the emergency and relief agencies during the first half of 1936 declined steadily and was less than for the same period the year before. On the other hand, loans made by the production-credit associations alone increased during the first half of 1936 and were larger than for the same period a year earlier.

After the midyear, however, the drought increased the demand for short-term credit of a relief nature, which had fallen off in the spring months of 1936. Emergency crop loans and drought-relief loans outstanding have steadily increased since 1929 and 1930 and now constitute more than 40 percent of the total outstanding short-term credit administered by the Farm Credit Administration. In addition, loans or grants in the more distressed cases are being made by the Resettlement Administration.

AGRICULTURAL TAXES

Tax levies per acre on farm real estate have changed on an average very little in the last 3 years. They run about 54 percent above prewar (1913) level and about 36 percent below the level of the peak year 1929. Factors governing the farm-taxation trend include, of

course, the volume of the farm income, the expenses of local and State government, and the extent to which taxing bodies rely on the property tax for revenue. With respect to all these factors there are some favorable indications.

As indicated earlier in this report, the outlook for the national farm income is favorable despite this year's drought, though the regional distribution will be extremely abnormal. There is a possibility of continued economies in local and State expenses. Further drastic cuts, however, are unlikely as great curtailment has already been accomplished; moreover, local bodies may have to assume more responsibility for activities recently supported heavily by Federal aid. As to the place of the property tax in State and local revenues, progress is being made toward developing additional sources, and toward shifting part of the burden from real estate to other forms of taxpaying ability.

Some of the reductions that have been made in farm-realty taxation are the result of curtailment in essential public services. For example, school terms have been reduced and teachers' salaries lowered. School budgets, in fact, have been drastically cut in many areas. Relief and rehabilitation expenditures have been extremely heavy, but the diversion of these expenditures to State sales and to Federal taxation has been a factor in lowering the farm-tax burden. As yet not much farm-tax relief has come from the reorganization of local and State governmental machinery, though this method offers important opportunities.

Improvement in farm income will have a dual effect on the farm-tax situation. It will decrease the burdensomeness of any given tax payment, but it will also lessen the economic pressure toward further tax decrease and even toward continuation at the present level. As mentioned above, many of the decreases in real estate taxes during the past several years have been made possible by curtailment of basic governmental services. Such curtailments have in many communities been deplored and have been considered only temporary expedients. With further improvement in the economic situation and in farm income there undoubtedly will be a decided tendency to restore the curtailed services to their previous levels. The tendency probably will extend also to increases in any services which before the recent curtailment had been locally considered as inadequate.

Over a long period of years preceding 1929 there had been a practically continuous increase in average farm real-estate taxes per acre for the country as a whole. This is demonstrated by a preliminary index computed by the Bureau of Agricultural Economics for the period 1890 to 1913, coupled with the Bureau's current series (1913–34) and a preliminary 1935 estimate. These series indicate an increase of about 267 percent in farm real-estate taxes per acre from 1890 to 1935. General price levels for the period increased about 40 percent, but even if adjustment is made for the price factor, there remains an increase of over 160 percent in farm real-estate taxes per acre. This figure of 160 percent should not be assumed to be altogether accurate, because changes in the general price level may not well represent changes in the composite price of governmental services, but it is believed to be a useful approximation for

the present purpose. On the assumption that local-government efficiency remained the same, these increases beyond the increase in prices should largely represent increase in governmental services.

The importance of this trend as it affects the future is its suggestion of a more or less constant demand for expansion of the services furnished by local and State governments. So long as such demand continues, there probably will be a decided tendency for farm taxes to increase in periods when farm income is relatively satisfactory and taxes are consequently less burdensome. The effect of this again will be influenced by any substitution of other tax sources for real-estate taxes.

There is heavy accumulated delinquency in farm taxation in many States. The acreage delinquent seems to have reached a maximum in 1932. Probably the amount of taxes delinquent continued to increase until 1934. These arrears, which farmers are beginning to pay up, often exceed their current tax bills, and farmers' tax payments in many cases will similarly exceed their bills for current taxes.

MARKETING AGREEMENTS

Marketing programs authorized in the original Agricultural Adjustment Act and modified under the subsequent amendments continue to help farmers to sell milk, fruits, and vegetables to better advantage. As of July 1, 1936, there were in effect 39 marketing-agreement, order, or license programs. They included 21 licenses and 3 orders for fluid-milk markets, 1 marketing agreement and 1 license for the national evaporated-milk industry, 1 marketing agreement for the national dry skim-milk industry, and 11 marketing agreements supplemented by 4 licenses and 6 orders for 11 such crops as fruits, nuts, and vegetables. With processors, handlers, and farmers' cooperative associations acting together under these programs, destructive competition has diminished, and more stable marketing conditions have been established. Launched as emergency measures, the programs have come to be valued for permanent use. Many of the more successful have been built on foundations already laid by the farmers' cooperatives. Others have given the initial impulse to cooperative marketing in various localities. They have helped farmers to coordinate marketing with production and to apply up-to-date methods of sorting, grading, and distribution.

After the decision of the United States Supreme Court in the *Hoosac Mills case*, it became necessary to reorganize the administrative set-up for dealing with marketing programs. Marketing activities that had previously been handled by the commodity divisions of the A. A. A. were centered in the Division of Marketing and Marketing Agreements. Meantime, regional divisions were established for administering the Soil Conservation and Domestic Allotment Act. The A. A. A. continued to develop and administer marketing programs, because the sections of the act relating to these activities were not before the court in the *Hoosac Mills case.* In subsequent suits, however, the marketing-agreement provisions of the Agricultural Adjustment Act have been questioned. The issue is whether the Hoosac Mills decision did or did not invalidate the marketing-agreement features along with the crop-control provisions of the act.

Final determination of the matter awaits action by the Supreme Court. In two out of three cases considered by Federal district courts, the marketing-program provisions of the Agricultural Adjustment Act have been upheld. In *United States* v. *Hugh David Edwards*, Judge Yankwich, of the United States District Court for the Southern District of California, found the marketing-agreement and order sections of the act to be separable from the crop-adjustment and processing-tax provisions. In *United States* v. *David Buttrick et al.*, Judge Brewster, of the United States District Court of Massachusetts, took a contrary view. He held that the marketing-agreement and order provisions were inseparable from the crop-control and processing-tax provisions. Later, in *United States* v. *Jerry Buckley et al.*, Judge St. Sure, in the United States District Court for the Northern District of California, continued in effect a restraining order that had been issued to halt violations of an order issued by the Secretary regulating the handling of deciduous-tree fruits.

As required by the amendments to the Agricultural Adjustment Act which were approved August 27, 1935, the Administration is replacing licenses with orders and carrying out the other requirements of the amended act. It has been possible to establish for various milk areas conditions tending to give all the producers an equitable share in the market. The agreements and orders usually provide for the classification of milk according to its use by the handlers; for the payment of minimum prices by handlers, and for the payment of uniform returns to producers under pool plans. Programs for the marketing of fruits and vegetables are simpler. They deal principally with the rate at which produce is shipped to market and tend to adjust market supplies more nearly to the prevailing demand. They affect, of course, only commodities already produced and ready for market. Additional programs are being developed at the request of producers and handlers, with the latter group showing an increased recognition of the fact that they have a common interest with farmers in the maintenance of fair prices to producers.

Surplus-Removal Operations

Surplus-removal operations have been developed as a supplement to the marketing-agreement programs. The authority is section 32 of the amendments of August 1935 to the Agricultural Adjustment Act. This section makes available an amount equal to 30 percent of the annual customs receipts for the encouragement of exports and the diversion of surpluses to other uses. Congress has subsequently amended it so as to include Government purchases of surplus farm products for relief distribution. The funds it makes available are in addition to congressional appropriations for the purchase of surplus dairy products for relief distribution. Operations under the section have dealt effectively with a number of farm-surplus situations, though the method is not universally applicable.

Advantages have resulted both to producers and to the needy. Surpluses that might otherwise have gone to waste have been moved into consumption, with a net gain both in farmers' prices and in food consumption among low-income groups. The purchases for relief

distribution have included apples, citrus fruits, prunes, pears, dried beans and peas, onions, turnips, cabbage, carrots, and eggs. In addition, the funds available under section 32 have made it possible to find new uses and new outlets for some farm products. More than a dozen surplus-diversion programs are in operation, under agreements between the Secretary and organizations of producers and handlers. They include programs for walnuts, pecans, raisins, prunes, dried figs, California fall and winter pears, dark air-cured and fire-cured tobacco, peanuts, and cotton.

The diversion programs authorize purchase of the commodities on the basis of grades or other requirements, at prices approved by the Secretary of Agriculture. The industry groups sell the products to anyone who will contract to convert them into byproduct or other authorized uses. Differences between the prices received and the prices paid for the products, plus incidental handling costs, are made up out of section 32 funds. Other types of diversion programs do not involve agreements between the Secretary and any industrial group. In these cases the diversion payment goes directly to individuals who comply with the requirements. For example, in a program designed to increase the exportation of pecans, the diversion payment went to the exporters and represented the difference between the domestic buying price and the export selling price.

The benefits have much exceeded the costs. Purchases of prunes for relief distribution involved only a small outlay; but the operation prevented a disastrous break in prune prices, and in fact caused an advance in the market for the entire crop. Frequently the diversion of surpluses into relief or other channels outside the usual course of trade brought about an increased distribution of the commodities through ordinary trade channels. It had this effect because the resulting price gain removed any incentive to let the products go to waste. Certain of the diversion programs include efforts to develop and expand uses for various products. In other cases, as for example, the export program for pecans, the programs introduced the commodity into markets previously unfamiliar with it.

Marketing Problems

The farmer's interest in marketing is less direct than his interest in production, because as an individual he must take the marketing system about as he finds it. It requires group action, such as the organization of cooperative associations or the passage of legislation, to make significant changes in the marketing system. There are some things the individual farmer can do. He may choose between grading his crop, or selling it field run; between selling it at harvest time or storing it; and between selling it to a local buyer or to dealers in central or terminal markets. Sometimes he can sell direct to the consumers. Federal inspection services, and the Federal market-news service, give the farmer increased facility in marketing. But as an individual there is not much he can do to lower the costs of marketing or to make the distribution system operate more smoothly.

Farmers believe, however, that substantial improvements can be effected through legislation and through cooperative action. They are impressed with the size of the national bill for transportation,

processing, and marketing. Even before the depression, in the decade of the 1920's, transportation, processing, and marketing absorbed about 55 cents of the consumer's food dollar. At the bottom of the depression these services absorbed about 67 cents. Since 1933 the proportion left to the farmer has increased, but it is not yet back to what it was before 1929. This fact is not in itself a proof that marketing and distribution are inefficient or extortionate; but it is evident that we need to be concerned with the cost of these services fully as much as with the costs of production on the farm. The whole subject needs thorough study; and farmers' organizations show an increasing awareness of the fact.

One way to reduce the costs of marketing and distribution is to suppress unfair and dishonest trade practices and to prevent racketeering. Enforcement of the Perishable Agricultural Commodities Act, the Packers and Stockyards Act, the Grain Futures Act, and the Food and Drug Administration Act has had a salutary influence. Investigations by the Federal Trade Commission have raised the standards of commercial practice. Trade regulation by State and municipal authorities contributes to the same end; in fact, many phases of agricultural marketing are necessarily in State and local jurisdiction, since they do not affect interstate commerce directly. But the problem usually transcends local or State lines. It is obvious, for example, that the California artichoke grower has a direct interest in preventing an artichoke racket in eastern markets. In many cases Federal, State, and local authorities must cooperate in preventing unfair trade practices, and perhaps in working out coordinated programs for improvement.

Research and service agencies, both Federal and State, must go beyond the provision of commodity inspection and market news, and the suppression of unfair trade practices. There is need for a positive program to improve the marketing system. Much could be done to promote efficient, low-cost handling of commodities, and to improve both the placing and the timing of the distribution. Many crops do not yet go to all the places where they could be profitably sold, and do not reach all their possible markets at the most advantageous moment. There is a field here for significant improvement. But the problem is so intricate and involves so many aspects of intercommodity competition that cooperative study seems indispensable to effective Federal and State action.

Rapid Progress Unlikely

It is unwise to expect extremely rapid progress. Our delicate and complicated marketing system has evolved gradually, in response to gradually changing conditions. Sudden and drastic overhauling might wreck it. But adjustments here and there are urgently needed. Recent years have seen important developments to which parts of the marketing system have not become well-adapted. The growth of large-scale processing and distribution raises new marketing problems. Motortruck transportation, commodity exchanges, and direct buying also have an important bearing on the marketing process. Study of these matters is a necessary preliminary to the development

of a legislative policy that will be fair to producers, distributors, and consumers.

One part of the marketing machinery which obviously needs adjustment is the wholesale and jobbing markets for perishables. In many large cities the cost of marketing and distributing perishables seems unnecessarily high. City marketing facilities have not been fully adapted to the motortruck, to direct purchasing by chain stores, and to other recent developments. Competitive building of railway-terminal facilities has tended to split markets and has added to the costs of both buyer and seller. Trucking and rehandling could be greatly reduced in many large cities through better coordination of the available facilities. A related problem arises from the development of regional or concentration points in the country. Several types of regional markets have grown rapidly since the beginning of the depression, and continuation of the growth will require research to keep it on sound lines.

An alarming development is a tendency toward the exclusion of outside foods from some markets and some States. Local protectionism of this type is profoundly repugnant to the spirit of our institutions and diminishes the Nation's prosperity exactly in the same manner as the excessive development of international tariffs diminishes the volume of international trade. Among the causes of this country's prosperity in the past, free trade among the States ranks high; and no consideration of a purely local nature should be allowed to interfere with it.

In the handling of certain products, for example milk, health factors enter; and the right of the several States to impose and enforce sanitary regulations cannot be questioned. In other cases it may be necessary to limit free trade in order to prevent the spread of insect pests or diseases, or for other sound reasons of public policy. No one should object to such legislation when it really contributes to national welfare. But there can be little doubt that in some cases the welfare of consumers and similar considerations have been used as an argument for regulations the main purpose of which is to benefit one group of producers at the expense of other groups.

Such legislation, if it is effective at all, prevents efficient production and efficient marketing. If carried to extremes it will raise food prices and lower consumption without benefiting producers. Temporary advantages gained by producers in one locality may be nullified by retaliatory legislation in other localities. It is extremely important to maintain among the States as high a degree of free trade as is consistent with the other legitimate objects of public policy.

INSECT CONDITIONS

Climatic factors played an important part during the year in the abundance and destructiveness of many major insect pests. The tent caterpillar and canker worms continued to occur in outbreak numbers in many sections of the Eastern States, and to defoliate trees over rather large areas. In the same general region, however, the codling moth and the oriental fruit moth were less abundant than normally. One of the introduced sawflies which feeds on grasses and grains was unusually abundant and destroyed wheat plants in

certain parts of the upper Ohio Valley. Various kinds of cutworms were destructively abundant generally throughout the region east of the one hundredth meridian. The cotton boll weevil was less destructive than in average years. The cotton leafworm invaded the fields unusually early, stripping the plants over large areas in Texas and adjoining States in the Cotton Belt. The bollworm, or corn earworm, was more destructive to cotton than in any year since 1929, but was generally scarce in corn over the eastern half of the country. It occurred in outbreak numbers in many sections in the west, and caused material losses of tomatoes. The house cricket was unusually abundant in many localities in the East. The abundance of these and many other insects is affected rather directly by the weather conditions. Some kinds, for example the periodical cicada, which occurred this last spring generally throughout the United States, are little affected by changes in weather conditions.

A few of the less familiar insect pests, such as the vetch weevil, the pepper weevil, tomato pinworm, cherry scale, and vegetable weevil, were found in new localities. A scale insect which had not previously been reported from the United States was discovered in a limited area in California and eradicated by the cooperative effort of State and Federal agencies.

During the summer of 1935 grasshoppers occurred in outbreak numbers in several of the Western and Middle Western States, but not to the same extent as they did in 1934. During the 1935 season the application of poison bait left over from the previous year materially contributed to reducing their numbers and protecting crops in several of the more severely infested States of the northern Plains region, particularly North Dakota. Drought conditions in the spring of 1936 were, however, very favorable for the development of grasshoppers, and outbreaks, accompanied by material damage, occurred in Nebraska, Iowa, Kansas, Missouri, Oklahoma, Minnesota, Montana, New Mexico, Arkansas, and eastern Colorado. This condition was anticipated and State officials for those sections, where cooperative surveys had been made the previous fall, were fully informed as to the possibility of grasshopper outbreaks, together with the estimate of the amount of material that would be needed to combat them. The area surveyed did not include Missouri, Oklahoma, and Arkansas, and accurate information was not available as to the sections of these States where the outbreaks were expected.

Limited amounts of bait materials left over from the previous control campaigns or secured through local and State agencies were available in a few sections only. These amounts, together with those secured with the special congressional appropriation of $250,000, made late in June 1936, were not adequate to meet the need, and farmers were urged to secure and distribute additional bait to protect their crops and reduce the numbers which menace next year's crops. The grasshoppers developed into winged forms perhaps a month earlier than usual and in the absence of food and effective control moved generally throughout the area, including sections where they had not been abundant previously.

The great numbers of chinch bugs that entered hibernation in the fall of 1934 presaged the most-severe outbreak of this pest in 50

years. Fortunately, the cold, wet spring which occurred over most of the area was so destructive to the bugs that outbreaks developed only in a few sections. It was, therefore, not necessary to use the special authorization and appropriation for chinch-bug control in the summer of 1935, and only $48,000 was expended of the $2,000,000 provided as an insurance fund to protect corn from bugs of the first generation.

The European corn borer caused severe damage in limited areas along the eastern seaboard, particularly to sweet corn. With the aid of an allotment from emergency funds, a survey was carried on to determine its spread, distribution, and relative abundance throughout the previously known infested area. To determine the status in the known infested area, 1,124 townships and 64 counties of 11 States were surveyed. During this survey 5,817 fields and 32,578 acres of corn were inspected. This survey disclosed that there was a general increase in borer abundance through much of the infested area. To determine the possible spread of the borer into new areas, scouts visited 712 townships in 28 counties in 11 States, examining 14,690 fields, totaling 192,222 acres. New infestations were found in 237 townships, but all of these were adjacent to areas previously known to be infested. This indicates that the spread had occurred largely by natural means.

The infestation of screwworm, first discovered in the Southeastern States in the fall of 1933, continued but was very materially reduced, largely because of the adoption of methods of treatment and handling livestock recommended during the cooperative educational campaign in 1935. The special appropriation of $480,000 which provided for the cooperative educational campaign made it possible to acquaint stockmen and others throughout the newly infested area with the approved methods of combating screwworms. During the summer of 1935 screwworms were unusually abundant throughout the Southwest, where infestation has annually caused material losses to cattle, sheep, and goats.

The educational and demonstrational work on screwworm control was extended to this section in the spring of 1936, and is now being conducted throughout the area infested by this pest. The extension and continuation of the work is provided for by an additional special appropriation of $460,000. The low temperatures which occurred during the winter over much of this area, together with the effective effort of combating the screwworm in areas where it overwintered, urged as a part of the educational campaign, greatly reduced the number of screwworm cases throughout the infested area. While the research to improve control measures should continue, the cooperative educational work can be brought to a close during the current year.

Plant-Pest Control

The date palm scale, an important introduced insect which at one time appeared to be the limiting factor to the development of date culture in the Southwestern States, has been eradicated from the United States. Continued intensive inspections failed to disclose the presence of this pest, and eradication activities begun a number of years ago were discontinued at the end of the fiscal year. At the same

time the quarantine regulating the movement of date palms in the United States was withdrawn.

The restrictions governing the importation of plants likely to introduce this and other pests continue in effect. These and other regulations were studied, however, to determine whether conditions had altered sufficiently to justify modification of the requirements. Two special quarantines restricting the entry of pines were in fact rescinded, the evidence indicating that adequate protection was included under another quarantine.

Regular activities carried on in cooperation with State agencies for the control of plant pests were augmented by allotments from emergency funds to provide relief employment. Trained workers planned, organized, and directed the expansion of these activities so as to use relief labor effectively. At the peak of the active season 25,242 workers were employed in 1,497 counties in 44 States, and during the year the work provided 21,398,000 man-hours of employment. The regular activities expanded and benefited by this employment are: White-pine blister-rust control; gypsy-moth control; phony-peach eradication; citrus-canker eradication; barberry eradication; and the eradication of the Dutch elm disease. In some instances, including the gypsy-moth campaign east of the barrier zone, barberry eradication in Pennsylvania, West Virginia, and Virginia, and white-pine blister-rust eradication in the Appalachian Mountain States, the work was extended into sections not previously covered with regular funds.

The brown-tail moth, an introduced pest which has been present for many years in part of the New England States, though its spread into other sections has been prevented by the enforcement of a Federal quarantine, was combated in the infested area by relief workers employed under a special allotment. They destroyed millions of the webs in which the pest overwinters. The work of destroying wild cotton in southern Florida to eliminate the pink bollworm and protect the Cotton Belt against this pest, was expanded by relief employment. To lessen the risk of the spread of the dry-land form of the cotton boll weevil, of which wild cotton is a native host, relief labor employed under a special allotment located and destroyed 615,596 *Thurberia* plants in 163 square miles in the Tortollita Mountains of southeastern Arizona.

With the aid of emergency funds, the eradication of peach mosaic, a disease of major importance to peach culture recently discovered in certain western areas, was undertaken in cooperation with State agencies. This infectious disease materially affects the growth of the peach tree and causes the production of small knobby fruit of little commercial value. It was first discovered in Texas. A few infected trees were reported from western Colorado in 1934, and in the spring of 1935 thousands of infected trees were located in three western counties of this State. The only known way of combating the disease is to locate and destroy infected trees. Through the cooperative eradication effort thousands of infected trees were destroyed in western Colorado during the summer of 1935. Surveys so far conducted in 1936 disclose the presence of only a comparatively few infected trees in this area and demonstrate the effectiveness of the eradication work. Within the last few months the disease has

also been located in parts of California, Utah, and New Mexico. Plans to extend the eradication effort to these sections are being perfected. Outlying infections may have been established through the movement of infected nursery stock.

The Dutch elm disease, which threatens the destruction of elms throughout the country, is an important problem in plant-pest control. Only a small amount of regular funds was provided to combat this disease. Allotments have been made from emergency funds and the cooperative eradication work pushed. The personnel-selection requirement, the necessity for training scouts and workers, and the uncertainty as to when and in what amount funds would be available, increased the difficulties. A few infected trees were found at outlying points, notably at Brunswick, Md., and Norfolk and Portsmouth, Va.; Old Lyme, Conn.; and Indianapolis, Ind. The infected trees were promptly destroyed. In the more heavily infected area—within a 50-mile radius of New York Harbor—the work included not only the location and removal of trees known to be infected, but also the location and removal of sick and dying trees, which may not only harbor the disease but may also serve as breeding places for the insect known to transmit the disease. All but a few of the 14,000 or so infected trees so far discovered in the United States were destroyed at the close of the fiscal year. Scouting during the past spring and early summer—the season most favorable for the location of infected trees—disclosed the presence of only a few infected trees as compared with the numbers discovered during the comparable period in 1935. This appears to demonstrate the practicability of eradicating the disease by methods used, the only ones known to be effective.

Research on Insects

Research to determine effective ways of combating insect pests has continued along many lines. In the search for new insecticides, especially ones which will not leave harmful residues on the marketed food product, the chemists have synthesized more than 100 organic compounds which have been tested by the entomologists to determine their effect on insects. In the initial tests some 20 of these, mostly those in the azo group, were very toxic to insects and appeared to hold promise for use in combating at least certain kinds of insect pests.

Detailed studies of pyrethrum demonstrated that the chemical formula for the toxic principles from pyrethrum flowers is much simpler than had been believed. This discovery may make it possible to develop the active principles of these flowers synthetically. At present our only source for this valuable insecticide is the imported flowers, approximating 10 million pounds annually. New compounds of nicotine have been made. Two promising ones are prepared from nicotine and peat, one soluble and the other insoluble in water. These are being tested on various insects including the codling moth, the principal pest of apples. An improved method of analyzing small amounts of nicotine opens up new ways of using this material, particularly as a fumigant. It has been demonstrated that the nicotine present in certain common types of tobacco is not present as a glucoside. This discovery has a practical bearing on the

preparation of home-made tobacco preparations used for control of various insects.

Laboratory and field tests with organic insecticides, particularly derris and cubé, have brought many modifications in the recommendations for the control of certain insect pests. It has been demonstrated that these insecticides which do not leave residues objectionable from the standpoint of human health can be effectively used against a number of different truck-crop pests, such as certain cabbage worms and the Mexican bean beetle, and that they are effective against flea beetles destructive to growing tobacco. The further usefulness of these recently developed materials is evidenced by the determination that one application of sprays or dusts of derris or cubé is effective against the pea aphid over a longer period than other recommended materials such as pyrethrum and nicotine. The practicability of protecting sugar beets grown for seed purposes from destruction by curly top by the application of pyrethrum and oil as an atomized mist has also been demonstrated.

The low per-acre value of most cereal and forage crops prevents the use of direct measures to control certain important insect pests, and cultural and biological control methods are not always effective, particularly because community action is usually required. Various varieties and strains of these crops have shown marked insect resistance, and investigations along this line have been intensified. Certain strains of field corn have been demonstrated to have marked resistance to the European corn borer independent of the time of maturity of the corn. One of the important factors in cutting down infestation is a delayed tasseling common to certain inbreds. No resistant character has, however, so far been found in sweet-corn varieties and strains which is not directly associated with date of maturity. Strains of alfalfa entirely immune to alfalfa-aphid attack have been obtained by selection. Marked progress has been made in developing wheats suitable for California, Kansas, and Indiana conditions which are resistant to the hessian fly. A variety of wheat substantially immune to fly attack has been developed in California, and the incorporation of this characteristic in varieties suitable for commercial use is under way in cooperation with plant breeders.

Two varieties of soft red winter wheat highly resistant to fly attack have been discovered in Indiana. Certain varieties of hard red winter wheat have been discovered which may be utilized in producing suitable wheats for production in Kansas and surrounding States. Studies on chinch bug in sorghum and wheat have revealed that certain varieties of both of these crops show marked resistance to chinch-bug attack. The development and use of these may offer a means of avoiding the heavy annual losses, including those occurring during chinch-bug outbreaks, such as that of 1934. Certain varieties of field and sweet corn are definitely less susceptible than others to attack by the corn earworm. The practical possibilities of this discovery have not, however, been determined.

Investigations to determine the possibility of using predacious and parasitic insects as aids in combating injurious insect pests have been extended to new fields and include such pests as the pea moth, the lima-bean-pod borer, and the pea weevil. An allotment from the

sugar-processing-tax funds from Hawaii provided for expeditions to Africa, South America, and the Orient in search of natural enemies to aid in combating the Mediterranean fruitfly and the melonfly in Hawaii. The introduction of natural enemies of insect pests into Puerto Rico, including an expedition to South America, was supported from a similar allotment from Puerto Rican tax funds. Eight beneficial insects have already been recovered on that island, three of which are well established and are being recolonized in parts of the mainland. Cooperative observations in Cuba fully substantiated the previous reports that the parasite of the citrus blackfly introduced on that island in cooperation with the Cuban Government in 1930 is effective in controlling this pest and reducing the possibility of its reaching our shores.

Studies on the secretions from the larvae of those species of flies used in treating chronic ulcers and bone lesions disclosed that one of the secretions is urea, a well-known chemical, which is widely used and produced synthetically. Reports received from physicians and surgeons who cooperated in testing urea produced synthetically, and chemically identical with that in the fly secretion, suggest that it contributes to the healing of certain types of wounds and has a soothing and beneficial action on many kinds of skin infections as well as deep-seated wounds. This discovery, if supported by further investigations, may be of material benefit to the medical profession and may reduce human suffering.

CHEMISTRY AND SOILS RESEARCH

Chemists in the Bureau of Chemistry and Soils have long been engaged in developing useful products from agricultural raw materials such as straw, cobs, fruit, and vegetable culls, and other byproducts of agriculture. Farm byproducts constitute more than 60 percent of the material annually removed from the land. These materials are part of the farmer's assets, as they are the fruits of his labor and of the fertility of the land. The straw, stalks, hulls, and other residues of the leading crops amount annually to more than 260,000,000 tons and contain approximately 115,000,000 tons of cellulose, 66,000,000 tons of pentosans, and 53,000,000 tons of lignin. A large proportion of this material, now wasted, is available for industrial utilization.

Efforts by Department chemists to tap this reserve of potential wealth have yielded substantial results, among the more recent of which may be mentioned a process for making high-grade cellulose from sugarcane bagasse, methods for producing furfural cheaply from cobs or hulls, a continuous destructive-distillation process for making charcoal and useful chemicals from various crop wastes, and fermentation processes for the production of fuel gas, organic acids, solvents, and residual cellulose fibers from crop wastes.

For the utilization of surplus agricultural products and culls the chemists of the Department have developed processes for making commercial products from citrus fruits, a process for the extraction of starch for industrial uses from sweetpotatoes, and mold-fermentation processes for making organic acids from corn sugar. Improved methods of using cornstalks and cereal straws for making

high-grade papers have received much attention, though the competition of other raw materials impedes commercial progress.

Chemical research in the Department during the last year contributed materially to the growing fund of knowledge of the utilization of agricultural products and byproducts. In cooperation with the Texas Agricultural Experiment Station, and using laboratories furnished by local chambers of commerce, the Department's chemists further studied the utilization of surplus citrus fruits, culls, and byproducts. They gave special attention to the production of fruit juices and concentrates, alcoholic beverages, vinegar, marmalade, candy, and volatile oil. Several commercial firms cooperated. That this work is valuable is attested by the fact that the number of commercial plants utilizing citrus culls in Texas increased from 3 in 1933 to 17 in 1935. In the same period the amount of money paid annually to growers in that State for citrus culls increased from $10,000 to $250,000.

In California investigators studied the production of wines and brandies from surplus and cull deciduous fruits, the loosening of stick-tight walnut hulls by ethylene, the preservation of fruit and fruit pulps by freezing, and the production of sirups and concentrates from apples, pears, and dates. In cooperation with the Washington State College of Agriculture and Agricultural Experiment Station, the Department established a new laboratory at Pullman, Wash., known as the Fruit and Vegetable Byproducts Laboratory, where it will investigate the utilization of fruits and vegetables grown in that section.

Experimentation at Byproducts Laboratory

Work proceeded at the agricultural byproducts laboratory at Ames, Iowa, on the production of cellulose, paper pulp, destructive-distillation products, and fermentation products from crop wastes. In these studies the Department cooperates with Iowa State College. In cooperation with the New York Agricultural Experiment Station at Geneva, N. Y., the Department is investigating the utilization of grapes, berries, and other fruits in the manufacture of commercial fruit juices, wines, and beverages. In cooperation with Stanford University the Department is studying at San Francisco the pharmacology of insecticidal materials. In Louisiana with the assistance of the Louisiana Agricultural Experiment Station, the Department is investigating the influence of cultural conditions on the composition and workability of juices from different varieties of sugarcane and the prevention of deterioration in harvested sugarcane during short-time storage. In cooperation with the North Carolina Agricultural Experiment Station the commercial fermentation of cucumbers into pickles and related products under southern climatic conditions is being studied.

Commercial development of a process discovered in the Department for producing sweetpotato starch is going forward under the leadership of the Bureau of Chemistry and Soils, in cooperation with the Bureau of Plant Industry and the Mississippi Agricultural Experiment Station, at a plant operated by a farmers' cooperative association at Laurel, Miss. In cooperation with the Alabama Poly-

technic Institute the Bureau of Chemistry and Soils established a field laboratory at Auburn, Ala., to promote the industrial utilization of sweetpotato starch. The Chemical Foundation recently established a research fellowship in the Bureau to find new technical uses for sweetpotato starch. Studies are in progress in cooperation with the Mississippi Agricultural Experiment Station on the quality and composition of sirups prepared from different portions of sorgo stalks. Improved methods developed by the Department for making sorgo sirup and sugarcane sirup are being introduced in Mississippi. Alabama, and Florida. The Texas Agricultural Experiment Station recently demonstrated the use of farm-scale equipment in making high-grade sugarcane sirup by the Department's method.

Cooperation was extended from the Department to a commercial firm in developing the improved nitric-acid process for producing cellulose from bagasse. Cooperation with commercial firms advanced also the technique of utilizing byproduct milk sugar in fondants for confectionery, and in determining the yield and quality of paper pulp from wheat straw, flax straw, cornstalks, and artichoke tops. In the last-mentioned experiments the Department's investigators used patented equipment designed for the production of paper pulp from straw by a continuous soda cooking process at atmospheric pressure.

Fundamental Research on Proteins and Enzymes

Fundamental research in the Bureau of Chemistry and Soils dealt with the chemistry of proteins, enzymes, plant pigments, cuticle waxes of fruits, lignin, turpentine, resin acids, and vegetable oils; also with the chemistry and physics of soils, the chemistry and physics of elements and compounds in fertilizer materials, the pharmacology of insecticides that may contaminate fruits and vegetables, and with microbiology as it relates to food spoilage, food preparation and preservation, industrial fermentations, and the curing of hides and skins. As part of a basic-research program provided for in the Bankhead-Jones Act of June 29, 1935, the Bureau organized three new research projects. These are: (1) Research into the industrial utilization of the soybean and soybean products, (2) the chemistry of enzymes and of enzyme action at low temperatures, and (3) a study of the allergens of agricultural products. In addition, chemists and plant pathologists will cooperate in a Bankhead-Jones project for the study of plant viruses.

The work on soybeans and soybean products is going forward at the Regional Soybean Industrial Products Laboratory, which has been established at the University of Illinois, in cooperation with the agricultural experiment stations of the 12 Corn Belt States. Specialists from the agricultural experiment stations will cooperate with chemists and agronomists from this Department. The object is to improve the quality and increase the yield of soybean products, and especially to develop industrial uses for them. It will include the selection of types and varieties for particular purposes. In the fundamental studies of enzyme action several of this Department's bureaus will cooperate. Special interest attaches to the little-understood activity of enzymes at low temperatures because such activity

affects frozen and cold-storage products in many ways. The work on allergens should yield information about the chemical nature of the plant and animal products known to cause physical ailments such as rash, hives, hay fever, and asthma, in susceptible persons. It has been estimated that 10 percent of the population is allergic.

Anticipating the eventual need for motor fuels other than gasoline, the Bureau of Chemistry and Soils is expanding its investigations into the possibility of producing such fuels economically from farm products and byproducts. One line of research will explore the efficiency of the microbiological conversion of starch and sugars into alcohol or other liquid compounds having fuel value. In the production of industrial alcohol in the past, it has always been necessary to give due consideration to the possibility that the alcohol might be used in such a way that its potability would be of primary importance. However, in the production of power alcohol from farm products potability is not a factor. It is possible, therefore, that fermentative processes based on this conception of the function of the end product may yield greater amounts of liquid fuel at a lower production cost. It is planned to give careful attention to this phase of the liquid-fuel problem. The possibility of using solid fuels, derived from agricultural products, in internal-combustion engines will also receive attention.

The Soil Survey

Another branch of the Bureau's work is the soil survey. Fundamental knowledge about the soil is more important today than ever before and more generally appreciated. Efficient farming depends essentially on suitable adjustments in plant-soil relationships, and rational land utilization is impossible without knowledge of the soil and its capabilities.

During the fiscal year 1936 the Soil Survey Division, in cooperation with local agencies, mapped about 20,000 square miles of rural lands in 31 States, Puerto Rico, and Hawaii. This work completed the survey of Puerto Rico and brought the total area covered to more than half the arable lands of the United States. The soil survey of Hawaii will be completed during the present fiscal year.

At the present time the Department is cooperating with the agricultural experiment stations of the seven States having an interest in the watershed of the Tennessee River which, in turn, are cooperating with the Tennessee Valley Authority for expediting the completion of a detailed soil survey of this region. This survey is absolutely essential in developing systems of agriculture for the improvement of the land and the protection of the reservoirs.

Information obtained from the survey of areas in Western States has permitted an extension in the acreage of certain special crops, and has indicated the areas where the accumulation of salts and the development of alkali would be a menace to irrigation projects.

Progress has been made in the development of a system for rating the various soil types according to their productivity for adapted crops and an increasing number of published soil surveys contain tables showing the inherent productivity of the soil as well as its productivity under different systems of management.

The Soil Survey Division prepared a special report on the characteristics and distribution of various kinds of organic soils and peat in the Pacific Coast States. This report paid special attention to the problems of soil conservation and flood prevention.

In July 1935 the Department issued C. F. Marbut's work, entitled "The Soils of the United States", which constitutes the final section of the Atlas of American Agriculture. This gives the accumulated results of the Department's soil surveys and brings into a focus the findings regarding soils as gained by Dr. Marbut and his associates during the last 35 years. It contains maps showing the areas covered by soil surveys up to June 1934, the distribution of the soil groups, the distribution of the parent materials of soils, and the distribution of soils without normal profiles.

An especially important feature is a large map of the United States in 12 sections showing the distribution of the country's soils according to 137 differentiated and 6 undifferentiated soil groups. There is also information on the classification of soils, their geographic relationships, their derivation and development, and their profile characteristics, as well as their physical properties and chemical composition. This report is the culmination of Dr. Marbut's life work.

Soil Chemistry and Physics

The Bureau of Chemistry and Soils is carrying on research on the chemistry and physics of soils to develop fundamental knowledge on composition and properties which has an important bearing on soil classification, soil conservation, and soil utilization, as well as on variations in the yield, composition, and food value of crops. It is also studying the causes for nonfertility of certain soils, the effects of arsenical insecticides on soils, and the value of peat as a soil amendment. During the past year several important publications have been issued as a result of these investigations. One of them, Technical Bulletin 484, presents analytical data for eight soil profiles, representing six of the great groups of soils, which show that the colloids of the great groups of soils differ from each other and that there exists a chemical basis for the characteristics of soils as manifested in the field. Another, Technical Bulletin 482, reports the results of studies on the occurrence of selenium in the soils of the United States. A second bulletin on this same subject is in process of publication.

Additional seleniferous areas have been found which produce toxic vegetation. Results of recent surveys indicate that toxic seleniferous areas are ordinarily found in certain geological formations. New areas where the soils are likely to be seriously seleniferous, judging from geological data, are now being explored. There seems to be no definite relation between the quantity of selenium in a soil and the quantity taken up by plants growing on it. The distribution of selenium in soils has been shown to be very widespread, and its primary source appears to be from volcanic activity. Its occurrence in small quantity in wheat appears to be world-wide.

Soils from the erosion experiment stations were studied with regard to the relationships between their physical constants. The same soils were examined by newly developed methods for certain elements which occur only in minute quantities and are not ordi-

narily included in soil analyses. Selenium, arsenic, copper, cobalt, nickel, zinc, barium, chromium, and vanadium were found in determinable quantities in each of the 11 profiles examined. The quantities varied from less than 0.1 part per million for selenium, cobalt, and nickel to as much as 708 parts per million for barium.

It is becoming increasingly apparent that these and other trace elements play an important role in soil behavior, as well as in plant nutrition and the food value of agricultural products. More exact knowledge concerning the chemical composition of soils, including their content of trace elements, will be essential in connection with a very comprehensive and fundamental cooperative research project that is being planned by the Bureau of Chemistry and Soils to determine the effects of soil, fertilizers, climatic conditions, crop rotation, cultivation, and variety of plant on the mineral and other constituents of plants and the value of plants for food purposes.

FERTILIZERS

Fertilizer studies demonstrated that the elimination of filler from fertilizers would save the farmers of the United States about $7,500,000 annually. It appears also that the purchase of double-strength mixtures, which can be manufactured without difficulty, would result in substantial savings. Nationally, the United States is self-contained as regards the principal fertilizing elements, and scientific research in this Department has contributed to the development of commercial fertilizer production. Interest is turning now to the comparatively recent recognition of the fact that mixed fertilizers should contain neutralizing agents to prevent the development of soil acidity. Research is advancing the production of fertilizer mixtures that are nonacid forming. One useful method is the use of ground dolomitic limestone.

Interest is growing also regarding the proper placement of fertilizers with respect to seed and plants, and the Department has developed a granulating process for mixed fertilizers to prevent the segregation of materials. Recent work on calcined phosphate indicates that the plant-food value of this product is as high as that of commercial superphosphate, and that the calcining process offers attractive possibilities for the production of phosphate fertilizer at low cost. A process has been developed in the Department for the production of potassium metaphosphate from potassium chloride and phosphoric acid. This product holds much promise as a fertilizer material because it consists almost entirely of potash and phosphoric acid and does not absorb moisture from the air. Also the Department has developed new compounds of urea with magnesium sulphate and magnesium nitrate which are useful for incorporating the secondary plant nutrient, magnesium, in fertilizer mixtures, as well as nitrogen.

New fundamental scientific knowledge has been acquired through basic research on the chemical and physical properties of elements and compounds contained in fertilizer materials, on the principles underlying catalytic action in industrial nitrogen-fixation processes, and on the fixation of nitrogen by living organisms and organic materials. The facilities of the Bureau of Chemistry and Soils for

modern physical and physicochemical research have been used to assist other bureaus of the Department having problems in this field. Thus, in cooperation with the Bureau of Plant Industry, the effect of X-rays on corn seed and tobacco plants was determined and spectroanalyses were made of the differences in the mineral elements content of toxic and nontoxic specimens of the roots of *Tephrosia* (*Cracca*) *virginiana* (devil's shoestring) which were under investigation as a source of insecticide.

Chemistry and the Farmer

Both hopes and fears cluster about the possibilities of chemical research and its bearing upon new uses for the products and by-products of the farm. Enthusiasts foresee important new markets and a quick solution of the whole farm problem. Warning voices say the chemist will synthesize foods in the factory and put the farmer out of his job. Industrial chemistry, they point out, has no particular preference for agricultural sources of raw material and may find what it wants elsewhere. Both the hopes and the fears should be discounted. There is no possibility either that chemistry will solve all the farmers' difficulties overnight or that it will do away with the need for farms.

The worth of a chemical discovery depends on the economic as well as the technical factors. Such things as cornstalks and cereal straw, for example, have some value as feed for livestock and as fertilizer. It pays the farmer to sell them for industrial utilization only when he receives more from their sale than they are worth to him as feed and manure. After the chemist has demonstrated that an industrial use for a farm product is possible, the manufacturer must test its commercial feasibility. Also, the farmer should remember that the development of new uses for one of his products may hurt the market for others.

In like manner we may discount the fears generated by the progress of industrial chemistry. Chemists have synthesized a small number of organic compounds formerly obtained from plants, but man must still apply to nature direct for food, clothing, and shelter. Probably agriculture will always have to produce most of the food substances that man requires, most of the clothing materials, and a good part of the materials required in providing shelter. In any case the change of emphasis is not likely to be appreciable in the near future. For as far ahead as we can see, chemistry will aid and not supplant the farmer.

There is, however, a side of the industrial-utilization problem which should be considered carefully. Chemical discovery, like other aspects of technical progress, is not necessarily an unmixed blessing, particularly to the farmer. If it opens new possibilities, it creates also a need for readjustment, especially when it affects intercommodity competition. For example, the utilization of sugarcane bagasse in the manufacture of rayon may diminish the demand for cotton. Soybean-oil production, stimulated by a demand for soybean products in the automobile industry, may come directly into competition with cottonseed and other vegetable oils. Sometimes, too, the devel-

opment of new uses for farm products attracts more people into farming and disturbs the balance between town and country.

Such considerations should not deter chemical research, for science cannot foresee all the probable consequences of its discoveries. That is beyond human wisdom. But the exploitation of particular products is not the only thing to keep in mind. Success in that direction will inevitably benefit some groups more than others, and public agencies engaged in chemical research should cooperate with other branches of the public service in promoting the most nearly equitable distribution of the benefits. There is special need for the collaboration of chemists and economists.

This Department endeavors simultaneously to promote the interests of producers, manufacturers, and consumers, because it is interested not only in the production but also in the commercial utilization and final consumption of agricultural commodities. While the work of the chemist in creating new uses for farm products may temporarily benefit some lines of production to the disadvantage of others, the Department believes the final balance will usually be in favor of the farmer.

It is important to prevent the unscrupulous exploitation of producers or would-be producers on false grounds. There are opportunities in parts of the United States for the culture of the tung tree. But land unsuited to that purpose is being sold to gullible investors. The same thing has happened in the case of hemp; and the sale of land is not the only means of diverting technical progress to improper ends. Everyone should understand that hard-headed cost accounting and commercial research are necessary to get the best results and that the laboratory discovery is only the first step, which may not be followed for a long time by the final demonstration on a commercial scale. In the files of this Department are recorded scores of chemical discoveries and innovations, which, though technically successful, remain unutilized commercially for years because the original costs were too high. For example, the Department developed a process, using dilute nitric acid as the pulping agent, for making high-grade cellulose from bagasse. But it was not until ways had been found to cheapen the production of the acid that the process became commercially practicable. Premature exploitation of research findings is a constant source of loss to investors and producers.

UTILIZATION OF DAIRY BYPRODUCTS

Investigations in the Bureau of Dairy Industry to develop ways to utilize whey or its separate constituents more efficiently have given promising results. The whey produced annually in the United States, as a byproduct in the manufacture of cheese, contains about 300,000,000 pounds of milk solids. Yet whey is commonly wasted or used only in limited amounts as feed for pigs and poultry. Dairy investigators have long considered this practice inefficient. They regard the feeding of whey to livestock as justifiable only until better methods of producing human food from whey can be developed.

Whey contains nearly half the food solids of milk. It contains all the valuable sugar and at least one vitamin, so that it possesses exceptional nutritive properties. Yet it has found few uses as

human food because it has no pleasing taste itself, and no special ways have been developed heretofore for using it. Within the last year the Bureau has found that whey may be used to enrich a variety of food preparations by taking advantage of its chief distinguishing characteristic, which is its lack of casein.

Casein is the substance that causes coagulation in milk under high temperatures or in the presence of acid vegetables or fruits. Manufacturers of vegetable soups can use condensed whey, whey powder, or whey cream in place of normal milk or cream to enrich their products. The whey solids will cause less difficulty with coagulation, the soups will retain their natural color better, they will have the characteristic milk flavor, and a greater nutritive value than soups made without milk solids.

The solids can also be combined with highly acid fruit juices, such as orange, grapefruit, strawberry, and similar fruits. Because of the high acidity of the combination little heat is required for sterilization, and these beverages and whips may be canned without a cooked flavor. By varying the combinations, sterilized whips, fruit drinks, and mixes suitable for freezing in a mechanical refrigerator can be made available to the housewife. These are probably only a few of the ways in which whey solids may be combined with other materials to improve old or create entirely new food products.

Young pigs will grow satisfactorily on pasture supplemented with whey, but it is often a problem to adjust the supply of whey to the requirements of the growing pigs. In the flush season there is likely to be a greater supply of whey than the pigs can consume. The Bureau's investigations indicate that surplus whey can be acidified with an active lactic-acid culture and concentrated at the factory to make an acid product that can be held until it is needed for feeding. Also, to provide for feeding roughage and whey when pasture is not available, concentrated sweet whey may be mixed with grass or alfalfa and ensiled. Preliminary trials show that pigs will consume this ration and make satisfactory growth.

Information developed in the Bureau's laboratories has found expression in a number of new commercial ventures. Cheese of the Roquefort type is now being made by a small factory which uses an abandoned coal-mine shaft for a curing room. The ideal natural temperature and humidity conditions of the shaft eliminate the necessity of providing artificial curing conditions. Arrangements have been made to start a similar operation in which a natural cave will provide the right conditions for curing. In one factory, with rooms artificially cooled and humidified, the Bureau's method for manufacturing a soft cheese of the Italian Bel Paese type has been established. A dairy-byproducts company has built and is successfully operating a factory for the manufacture of lactic acid by fermenting whey. A large volume of whey is being utilized.

Experimental shipments of concentrated frozen milk have been made to the Canal Zone under the Bureau's direction, to determine the feasibility of providing fluid milk in the Tropics, on shipboard, and in other places where good-quality milk is unobtainable or the supply is inadequate. Research in the Bureau has demonstrated that milk may be concentrated to one-third of its volume, or less, held at

temperatures below freezing for weeks, and then brought back to its original volume by adding water, without losing the characteristics of fresh clean-flavored milk.

ANIMAL INDUSTRY

Superior types of livestock continue to be one of the most promising means of increasing the efficiency and economy of production. Great variation in the growth of pigs, similar in outward appearance, has occurred at the National Agricultural Research Center, Beltsville, Md. Under the conditions of management and on identical rations, pigs of the same litter varied as much as 100 days in the time required to attain a weight of 225 pounds. And within the same breed the quantity of feed required by different litters to make 100 pounds of gain varied from 325 to 500 pounds. Such observations indicate the feasibility of selecting the breeding hogs that are naturally fast and economical growers. There are indications also that rapid growth is associated with tenderness in meat.

Studies with Danish Landrace hogs imported a few years ago have now reached a stage to permit comparisons with American-bred hogs. When the chilled, dressed carcasses of 40 Landrace hogs and 36 of 2 American breeds were compared, the former had the higher percentage of ham, loin, and bacon and lower percentages of picnic shoulder and head. The higher yield of bacon in the Landrace hogs is especially noteworthy. In general, the Landrace hog excelled in the production of the more valuable cuts of pork.

In the study of more efficient cattle production, the Department has sought a type of animal that will produce beef profitably under adverse conditions of heat and insect pests. Such cattle are especially needed in the Gulf coast region and in other sections having a similar climate.

Crosses between Brahman cattle and several beef breeds already established in the United States have given promising results. Cross-bred types developed from the Guzerat (Brahman) and the Aberdeen Angus breed have shown high adaptability to semitropical conditions. The second generation of calves carrying three-fourths Aberdeen Angus blood and one-fourth Guzerat have, in all instances, been polled and black. A noteworthy result is the increased weight, at weaning age, of cross-bred calves over purebred Aberdeen Angus calves. First crosses, containing 50 percent of the blood of each breed, averaged 455 pounds, whereas Aberdeen Angus calves averaged 391 pounds. Second-cross calves, possessing three-fourths Aberdeen Angus and one-fourth Guzerat breeding, averaged 491 pounds at the same age. These results are in the direction of improvement both in adaptability to the region and in desired market characteristics.

Other breeding studies have been supplemented with tests on the tenderness of the resulting meat. Four years' experimental work has shown that roasted rib cuts from grade Hereford cattle were more tender than corresponding cuts from cattle of native breeding slaughtered at the same age. These studies indicate the presence of hereditary differences in fat distribution and tenderness.

In a comparison of methods of wintering cattle under western-range conditions experiments showed wide differences in costs. When breeding cows were kept on reserved creek bottom and allowed to graze sagebrush range supplemented by 83 pounds of cottonseed cake per cow, the wintering cost per animal was $2.84. The cost of wintering similar cows on alfalfa hay at the rate of 765 pounds per head was $4.51. Experiments of this kind indicated the economies possible by altering systems of management. When applied to large herds of cattle, even small differences of the kind cited result in large savings and impressive net profits.

A valuable scientific aid in sheep breeding and in the raising of other animals for hair or fur is a device recently developed in the Department's animal-fiber research laboratory. The instrument makes possible the procurement and study of very thin cross sections of fiber in a few minutes' time. The various characteristics of fiber associated with suitability for commercial purposes are readily observed by the use of this device. Already it is being used in many fields of industry. Still another instrument developed in the same laboratory during the year makes possible the measurement of length and crimp of wool and hair fibers in a more accurate and efficient manner than with previously available equipment.

Foreign Breeds Introduced

In connection with improvement of animal types the Department has obtained from various foreign sources species and breeds of livestock having noteworthy characteristics. Such stock, introduced in 1935 and 1936, includes Nonius horses and Puli sheep dogs from Hungary, red Danish cattle from Denmark, and south Devon cattle, large black hogs, white Austrian turkeys, and White Wyandotte chickens from England. After receiving veterinary inspection and meeting other quarantine safeguards these animals were admitted to Department experiment stations for breeding and feeding studies and related observations. To some extent also they are being used in cross-breeding experiments with selected types raised in the United States.

Security From Livestock Diseases

Each year the livestock industry of the United States becomes more secure from diseases, parasites, and other pests. Through methods supplied by scientific research, stockmen and their veterinary allies have recently extended the frontiers of animal health very materially. A brief appraisal of the animal-disease situation at the end of the last fiscal year indicates several noteworthy advances in this field.

Bovine tuberculosis has been practically eradicated from 40 of the 48 States in the Union and from 95 percent of all the counties. There is considerable need, however, for continued retesting of herds to locate and eradicate any remaining infection. Cattle carcasses which, because of tuberculosis, failed to pass Federal inspection at the principal livestock markets numbered less than 10,000 in 1936 as compared with more than 28,000 the previous year. Condemnations of parts of cattle carcasses likewise were much less, being about half as many as during the previous year. A reduction in tubercu-

losis, though in less degree, was observed also in swine. These figures, based on official veterinary inspection of millions of animal carcasses, signify a large saving of meat as well as an unmistakably improved condition in the health of cattle and swine.

Extensive public interest in the elimination of Bang's disease, or infectious abortion, has caused the Department to continue the testing of cattle in cooperation with State officials and livestock owners. Agglutination blood tests for the detection of this disease were applied to approximately 6,600,000 cattle. About 7 percent were reactors as compared with 11 percent during the preceding year. The elimination of Bang's disease, which has in the past caused heavy losses and much discouragement in cattle breeding, has resulted in greater optimism among dairymen and others whose herds have thus been placed on a more secure health basis.

In search of an improved diagnostic agent for the identification of cattle affected with this disease, the Department recently developed a biological product known as a stained antigen for the purpose. This product makes possible a rapid whole-blood test, which has several practical benefits over the present slower and more expensive methods of diagnosis. A thorough field trial of the new method was begun by the distribution of sufficient stained antigen for testing 13,000 cattle under Department supervision.

In the eradication of the cattle fever tick the area in continental United States still under Federal quarantine has been reduced to only 9 percent of its original size. The sections still infested with ticks are confined to parts of three States—Florida, Louisiana, and Texas—in contrast to infestation of 15 States when the work began in 1906. Systematic eradication of cattle ticks was recently begun in Puerto Rico.

Control of hog cholera has reached the point where immunization by the serum-virus treatment, developed by the Department, is largely a routine procedure. The method is widely known; serious outbreaks of the disease are infrequent; and the Department has largely relinquished direction of control work to the States. However, it continues to supervise the preparation and distribution of the virus and serum, of which a total of more than 500,000,000 cubic centimeters was produced last year under Federal licenses. As a means of assuring adequate production of these products for possible emergencies, the Department has aided manufacturers in perfecting a marketing agreement directed toward this end.

A New Immunizing Product

As a still further measure of hog-cholera control, the Department recently developed a new immunizing product. Known as crystal-violet vaccine, this product has given distinctly encouraging results in experimental trials. It has provided approximately 99 percent satisfactory protection and has several advantages, including greater safety, over the familiar serum-virus method of immunization. During the last year commercial production of the vaccine on a small scale was sanctioned by the Department in order that this new product might be thoroughly tested under various field conditions. Until the merits of the vaccine are more thoroughly established, however, reli-

ance must still be placed in the serum-virus treatment, the efficacy of which, when properly administered, has been fully established. A present limitation of the crystal-violet-vaccine method of immunization is its slowness in furnishing protection. Immunity does not appear to be established usually until at least 2 weeks after a hog has been vaccinated.

The drought of 1934, with resulting extensive shipments of livestock, retarded several lines of livestock disease-eradication work. Some spread of scabies in cattle and sheep occurred in Central and Western States, but scabies of horses now appears to have been eradicated, inspections revealing no cases during the year. The eradication of the horse disease, dourine, likewise appears to be virtually accomplished, but State authorities are continuing the quarantine of a few areas where the presence of the disease is suspected. Any remaining infection is considered to be very slight, judging from the evidence of only one animal giving a positive reaction to this malady within the last year.

A comparatively newly identified disease of horses and other equines has caused anxiety as well as serious loss in several localities. Known as infectious encephalomyelitis, and occasionally by such nonspecific terms as blind staggers, brain fever, and sleeping sickness, this malady has appeared in no less than 20 States. It is caused by an infectious virus which produces nervous symptoms resulting from inflammation of the brain and spinal cord. The mortality is high, and in animals that recover there may be permanent impairment of the brain. Outbreaks occur chiefly during the summer and fall months and in low-lying and moist areas. The use of a specific serum has been helpful in preventing the spread of infectious encephalomyelitis, but it produces only a short-lived immunity. The Department is studying the disease and testing various biological products and drugs reported as being beneficial for its prevention or treatment.

Anthrax caused comparatively slight loss during the year, no serious outbreaks being reported to the Department. Assistance in preventing the disease was given to Indians on reservations where outbreaks occurred several years ago. The horse disease, glanders, which at one time caused heavy losses, has been practically eradicated.

Recent research has disclosed several highly effective methods of combating injurious internal parasites, such as kidney worms of swine and liver flukes of cattle and sheep. Livestock owners have been quick to adopt and apply the Department's recommendations. In several instances supplementary benefits derived have greatly exceeded the original purpose of control methods.

For instance, Department investigators have shown that drainage of wet, marshy, and boggy pastures is the most practical procedure for controlling liver flukes. In several areas these parasites were killing as many as 50 percent of the sheep and stunting or killing calves. The broadcasting of copper sulphate to destroy the snail intermediate host is, at best, only a temporary expedient and must be continued from year to year in order to insure the destruction of the fresh crops of snails which reappear sooner or later. Drainage, on the other hand, is an effective bulwark against aquatic snails, which invariably perish on dry land. Recently reclaimed boggy meadows contained thousands

of dead snails, many of which were the potential and actual conveyors of the liver fluke that is deadly to sheep and injurious to cattle as well as to several species of wild animals.

But besides controlling liver flukes, the drainage of wet pastures has produced a marked change in the type of vegetation. The coarse aquatic grasses containing little or no nourishment for livestock gradually disappear as the pastures become dry; and, as a result of natural seeding, highly nourishing forage, including clover, timothy, and other nutritious plants, take their place. This results in a permanent improvement of the land; and, with reduced water in the soil, the land produces good forage earlier in the spring and later in the fall.

In the Western States where liver-fluke control is in progress drainage of marshy meadows makes considerable water available for irrigation. In Utah, particularly, the water from the drainage ditches is being diverted into irrigation canals, thereby adding materially to the supply of water available for irrigation. Incidentally drainage of wet and boggy lands has considerable value as a mosquito-control measure.

In short, the control measures for liver flukes are not only effective in reducing serious losses in sheep and stunting in cattle but are also of marked value in converting submarginal lands into productive pastures, adding to the available water supply of areas dependent on irrigation, and aiding in the control of mosquitoes.

Pullorum disease, a major drawback to poultry raising, is being controlled by progressive flock owners through the use of the rapid whole-blood test developed by the Department a few years ago. Commercial production of the stained antigen used last year in making the test was sufficient for testing more than 10,000,000 fowls. Under the provisions of the national poultry improvement plan thus far adopted by 34 States, the Department approves the quality of all this antigen used in official testing, thus insuring a high quality of this diagnostic agent.

Besides these advancements in curbing losses from livestock diseases, the Department has continued its quarantine and inspection services against the possible introduction of infection from abroad. During the year the United States remained entirely free of foot-and-mouth disease, rinderpest, surra, contagious pleuropneumonia, and other maladies that cause heavy losses to livestock owners in some foreign countries.

The increase of about 7 percent in enrollment reported by the 10 federally accredited veterinary colleges of the United States augurs well for continuing the foregoing measures for the protection of the Nation's livestock.

Supervision of Livestock Marketing

Supplementing its regulatory work of veterinary character, the Department has sought to improve conditions of livestock marketing. Several noteworthy developments of the year resulted from procedures under the Packers and Stockyards Act.

Three cases involving orders of the Secretary which prescribed reasonable commission rates and stockyard charges at Chicago, Ill., and St. Joseph, Mo., were upheld by the United States Supreme

Court. As a result legal action has been taken in the lower courts for the return of excess commissions and stockyards charges to shippers. The amount of such returns involved probably will exceed $1,000,000. The decisions of the Supreme Court were important and significant in that they sustained procedures followed by the Department in determining stockyard charges and commission rates.

Congress amended the Packers and Stockyards Act during the year to include the supervision of poultry marketing in a manner similar to the supervision of the marketing of other classes of livestock. The amendment provides for the licensing of persons engaged in furnishing facilities or rendering services for marketing live poultry in interstate commerce in cities designated by the Secretary of Agriculture. The regulation of rates and practices of licenses is a further provision of the amendment.

Investigations of the poultry-marketing situation, together with requests for supervision from a number of cities, resulted in the designation of poultry markets in 15 cities as being subject to Department supervision, up to the close of the fiscal year 1936.

FORESTRY

Most people have regarded forestry as largely a means of assuring an adequate future supply of timber, and it should, of course, be valued for that purpose. Four-fifths of our commercial forest land, and at least 90 percent of its potential productivity, are in private ownership; and private ownership has not generally endeavored to maintain a continuous timber harvest. It is extremely important, therefore, to promote sustained-yield practices on the publicly owned forest land and to encourage such practices on the privately owned land. Sustained forest production is essential for the general welfare. But forestry has other ends as well, notably the conservation of soil and of water—in other words, the prevention of erosion and of floods. Fortunately, the methods which conserve timber productivity at the same time promote the other objects of scientific forestry so that no conflict arises. Curbing forest exploitation is good for the timber industry and also for the public interests that depend upon the forests. This Department recommended, and Congress in part approved during the last year, a program for coping with some of the responsibilities involved.

That a common interest extends to all forest lands and that private, as well as national, forests ought to be managed on a sustained-yield basis is now generally acknowledged. There is a public, as well as a private, obligation. Accordingly, fire protection by the Civilian Conservation Corps under the direction of the Forest Service is under way on private, as well as public, forest lands. The expenditure on private lands for this purpose has already exceeded $58,000,000. For the current fiscal year Congress has appropriated increased funds for forest-fire protection by Federal agencies in cooperation with the States and with private owners. Forest research carried on by the Forest Service similarly benefits public and private land ownership, through its influence on the utilization, as well as the production, of timber.

Federal acquisition of forest lands through purchase was first authorized in 1911, national forests previously having been set aside only from the western public domain. Prior to 1933, however, the Federal acquisition of forest lands never exceeded 550,000 acres in any one year. The total area approved for purchase was only 4,727,680 acres in the first 22 years of the program. In 1933 Congress authorized accelerated activity, and the area acquired in the 3-year period ended June 30, 1936, exceeded 11,400,000 acres. The acquisitions in the last fiscal year aggregated 2,998,060 acres. Besides adding to the system of federally owned and managed national forests this accelerated program assured county governments of future revenue from lands that might otherwise have been tax-delinquent, and harmonized with other aspects of the national agricultural policy. The national forest system now covers more than 170,000,000 acres in 37 States and 2 Territories.

Advantages resulting from the Federal ownership and multiple-use management of forest lands are substantial and varied. They include protection to watersheds, conservation of merchantable timber, scientific management of more than 83,000,000 acres of livestock range, preservation of wildlife, particularly big game and fish, provision of recreational facilities, and soil and water conservation, with resulting benefit to power development and irrigation. They afford innumerable opportunities for recreation; more than 17,000,000 persons visited the forests last year for rest and relaxation. Administered by the Forest Service under a system of coordinated use, our national-forest resources furnish support directly to more than 1,000,000 persons. Modern forestry thus includes more than producing continuous crops of timber. It comprises the planned management of forest, range, and wild lands, and of their many resources; it has to do with conservation through the use of organic resources and services in the interest of general welfare.

Forest Protection and Flood Control

How important it is to protect forest, range, and other vegetative cover so as to retard the water run-off and prevent erosion becomes evident when floods occur. For example, Pickens, Frankish, and San Dimas are mountain canyons opening out into fertile valleys of southern California. Fire denuded 5,000 acres in Pickens Canyon in 1933. Fire similarly swept Frankish Canyon in 1935. Fire did not visit San Dimas Canyon. On New Year's Day 1934 a flood swept out of Pickens Canyon, destroyed 200 homes, and killed 34 persons. Though the same storm hit nearby San Dimas Canyon, it caused no flood there. This year in January and February floods swept out of Frankish Canyon through the cities of Upland and San Bernardino. Though the same storm struck the unburned San Dimas Canyon, it did not precipitate a flood there.

Near Centerville, Utah, in 1930 overgrazing was the primary cause of a flood which wrecked homes and buried orchard lands under soil, rock, and debris. There was no flood from a nearby watershed that had been properly grazed. Floods come less frequently and have lower crests where a vigorous vegetative cover remains.

Reservoirs and distributing systems that carry water to some 20,000,000 irrigated acres had a value in 1930, according to the census, of more than $1,000,000,000. Many billions have been spent for downstream engineering to control floods that start with small streams and additional sums for removing silt from navigable waterways. The Federal Government has incurred most of this expense. Yet it has invested less than $70,000,000 to purchase lands where floods and erosion begin, and less than $14,000,000 for replanting denuded forest and range lands. One of the best and cheapest ways to prevent soil erosion and combat the danger of floods is to reclothe denuded slopes with forest and other vegetative cover. In dealing with the flood problem, prevention is better than cure.

As a flood-prevention measure, the Federal acquisition of 81 million acres of lands on important watersheds in 27 States east of the Rocky Mountains has been recommended. Such lands should be protected, revegetated where necessary, and administered as parts of our existing national forests. The Forest Service has outlined an expanded program and recommended it to Congress. Preventive measures in foothills and mountains will help to conserve investments already made in downstream engineering. Without such preventive measures the work downstream may not have much effect.

In the fall of 1934, following the great drought of that year, the Forest Service began to plan shelterbelts in the Great Plains. Such shelterbelts serve as barriers against soil drying and wind erosion. They help to catch and retain snow, and to delay the surface run-off. The shelterbelt planting was not started until the problem had been thoroughly studied, surveys made of existing shelterbelts, and analysis completed of 25 years' experimental work by Federal bureaus and State agricultural colleges. By agreement with farmers, the Forest Service planted about 7,000 acres in the spring of 1935. This year it planted nearly 24,000 acres, using 23,000,000 trees in the work. Examinations in June of all the plantings revealed an average survival of 81 percent, a highly satisfactory figure for any forest-planting operation. However, Congress decided to discontinue the Plains shelterbelt project and appropriated $170,000 to conclude the work and to dispose of the trees still remaining in the nurseries.

Report on Range Resources

In response to Senate Resolution 289 (74th Cong., 2d sess.), this Department made a special report on the original and present condition of our range resources. The report was prepared by the Forest Service. As required by the resolution, it dealt with the factors that have led to the present condition of the range, with the social and economic importance of range use and conservation, and with methods for restoring its productivity. Various Federal and State agencies furnished data for the report.

The western range is much larger and more important to the national welfare than most people realize. It includes some 728 million acres, or nearly 40 percent of the total land area of the country. It is the mainstay of a 4-billion-dollar western livestock industry, and includes four-fifths of the principal water-yielding areas on the watersheds of major western streams. Low precipita-

tion makes water the limiting factor in nearly all western development.

In the range country in 1930, according to the census, there were 775,745 farm units and nearly 400,000,000 acres of land in farms. Normally these farms grow 35 percent of the feed for western livestock. Except for highly specialized crop farming, mostly on irrigated land, western agriculture is primarily an integration of range-livestock grazing and crop farming.

Forage depletion for the entire range area averages more than 50 percent—the result of a few decades of livestock grazing. Range depletion on the public domain and grazing districts averages 67 percent; on private lands about 50 percent. Seventy-six percent of the area is still on the downgrade. No less than 589 million acres of range land is eroding more or less seriously, reducing soil productivity and impairing watershed services. Three-fifths of this area is adding to the silt load of major western streams. An outstanding cause of range depletion has been excessive stocking. Some 17.3 million animal units are now grazed on ranges which it is estimated can carry only 10.8 million.

Severe recurrent drought has contributed to this overstocking. Stockmen have been forced to damage the range, in order to meet their immediate obligations. Unsuitable land laws have made the range a bewildering mosaic of different kinds of ownerships and of uneconomic units. Most spectacular among the maladjustments of range-land use has been the attempt to use more than 50 million acres for dry-land farming. About half of this area, ruined for forage production for years to come, has already been abandoned for cultivation.

The national forests furnish indispensable summer range. The 83 million acres grazed by domestic livestock has improved so that it is now depleted only 30 percent; important water-yielding areas on national forests are being afforded proper watershed protection and it has been necessary to exclude livestock from only a comparatively small area. Research carried on by the Forest Service is showing how to manage range lands for stable forage and livestock production, how to reseed severely overgrazed range and abandoned dry farms in the range area, and how to coordinate grazing use with erosion prevention, flood control, and water delivery, tree reproduction, wildlife, and recreation.

PLANT RESEARCH

Excellent results continue to be secured with the two outstanding varieties of upland cotton introduced and developed by the Bureau of Plant Industry. These varieties are Acala and Lone Star. These two cottons, with the strains and varieties developed from them, are now annually planted on more than 1,000,000 acres in the Cotton Belt, distributed from Georgia to California. Practically the entire upland cotton acreage in the irrigated valleys of the Southwestern States—Texas, New Mexico, Arizona, and California—is planted to Acala. Because of its productiveness and superior quality of fiber, Acala has become outstandingly popular with growers in parts of Oklahoma and Arkansas, and in test plantings conducted for several years at State

and Federal stations in Texas, Acala has been shown to be especially well adapted to the great blackland soil area of that State.

One of the outstanding results of the past year's work concerns the Hopi cotton, a small-boll type grown, probably for centuries, by the Hopi Indians in northern Arizona. This cotton has a staple only thirteen-sixteenths of an inch long, but fiber studies and spinning tests conducted by the Bureau of Agricultural Economics show that it approaches sea island in fineness and produces a yarn as strong as that made from $1\frac{5}{32}$-inch upland cottons. The $1\frac{1}{8}$-inch fiber from a first-generation cross between Acala and Hopi produced a yarn as strong as that derived from $1\frac{1}{2}$-inch upland cotton.

Interest in sea-island cotton has greatly increased, both among former growers and among manufacturers desiring this finest of the world's staples for special textile purposes. In spite of the many hazards of production under weevil conditions in the Southeastern States, about 700 acres were planted in 1935 in northern Florida. Seed for this acreage was the increase from a small reserve stock furnished by the Bureau in 1934, through the Florida Extension Service, to a few growers for experimental demonstrations. Only 15 bales were produced on the 175 acres planted in 1934, but 170 bales were produced on the 700 acres planted in 1935, and sold at prices ranging from 25 to 28 cents a pound. As a result of the more favorable returns in 1935, about 4,000 acres were planted in northern Florida and southeastern Georgia in 1936.

The need for developing earlier and more prolific strains of sea island or a substitute for this cotton better adapted to present conditions has become acute. Special studies are being made, therefore, of hybrids between sea island and outstanding upland long-staple varieties to find a type combining the long, silky quality of sea-island fiber with the larger bolls and earlier maturity of upland. Approximately 8,000 hybrids were made in 1935, about 3,000 of these being sea island crossed on upland and 5,000 upland crossed on sea island. A system of convergent crosses, in which hybrids are back-crossed to one or both parents, is being used in an effort to establish pure strains having the desired combinations of fiber quality and plant characteristics.

Among the extra-staple upland cottons showing special promise as a substitute for sea island is a selection out of the Tidewater variety developed by a former sea-island breeder near Charleston, S. C., in cooperation with specialists of the Bureau. The new strain is much more productive than sea island, has bolls about twice the size, and produces a fine quality of fiber $1\frac{1}{2}$ inches long. The stock is being further selected and used in the hybridization work with sea island. Improved strains of Meade, an early upland variety, with fiber similar to sea island in length and quality, are also being developed for use in the studies of extra-staple cottons adapted to production in the Southeastern States.

The most important result in Egyptian-type cotton breeding during the past year is the establishment in commercial production of the SxP variety, derived from a cross between Sakel, the longest in staple of the Egyptian varieties, and the Pima variety of Arizona. Approximately 1,700 acres of SxP were grown in the Salt River Valley

in 1935, and the yields were so satisfactory and the market for the product was so active that the demand for planting seed in 1936 greatly exceeded the supply. Some 10,000 acres of this variety are being grown in 1936 in the Salt River Valley and neighboring districts. Production on this scale should determine definitely the position of this cotton in the markets as compared with that of Pima. If SxP can be substituted satisfactorily for Sakel cotton, large quantities of which are imported annually into the United States, a considerable expansion of the acreage of Egyptian-type cotton in the Southwest would be likely to result, and increased production should place the American-Egyptian industry upon a more stable basis.

Grains

The stem rust epidemic of 1935 was perhaps as severe as or even more so than those of 1904 or 1916. Late seeding in the spring wheat belt, delayed maturity of winter wheat in Kansas and Nebraska following late germination due to a dry fall and winter, a rank growth of wheat late in the season, unusually favorable conditions for the development of the rust, and an abundance of inoculum from the wheat fields of Texas, combined to produce the most widespread epidemic in the history of the Great Plains. The loss in North Dakota alone has been estimated at more than $100,000,000 and losses were proportionately as great in South Dakota and Minnesota. The winter wheat crop also suffered though not to so great an extent.

The Thatcher variety of wheat, produced as a result of research by this Department and the Minnesota Agricultural Experiment Station and distributed to farmers last year, withstood the epidemic remarkably well. Nominal damage only was suffered by this variety as compared with complete or nearly complete failure for the Marquis variety under similar conditions. Ceres, which is somewhat resistant to rust, was also severely injured, though not to so great an extent as Marquis. Thatcher has proved acceptable to the grain and milling trade and popular with farmers. The acreage is being rapidly increased.

Three other new varieties of wheat, produced as a result of the cooperative work of the Bureau, have recently been distributed to farmers. Rex, produced at the Moro and Pendleton, Oreg., field stations, was first grown commercially in 1934. Several thousand acres were seeded for the 1936 crop. The chief characteristics which commend this variety to farmers are its resistance to the principal races of bunt occurring in the Pacific Northwest, early maturity, winter hardiness, stiff straw, resistance to shattering, and high yields. It is recommended principally for the area south of the Snake River in Washington and Oregon.

Hymar, produced at the Washington Agricultural Experiment Station, is also highly resistant to the races of bunt most generally prevalent in the Pacific Northwest. It is popular with farmers chiefly because of a relatively high test weight and high relative yields with favorable conditions with respect to moisture. It is grown chiefly in the Palouse area of Washington north of the Snake River.

The quantity of water in the soil at seeding time is definitely related to the yield of winter wheat. Recent analysis of soil-moisture and crop-yield data obtained in experiments extending over a period of 26 years in the central Great Plains has developed principles by which the farmer may recognize at seeding time conditions that indicate high probabilities of failure or success and regulate the seeded acreage accordingly. The depth to which the soil is wet can be determined by observation, and is a good measure of the quantity of water in the soil. The prospect of a good crop increases with the depth to which the soil is wet. When wheat is planted in a dry or nearly dry soil, the probability of success is extremely low. At three stations in western Kansas the chances were 71 out of 100 that the crop would be a failure (4 bushels or less per acre), and there were only 18 chances in 100 of producing a 10-bushel or better yield. When the soil was wet to a depth of 3 feet at seeding time, the chances of failure were reduced to 10 in 100 and the chances of producing a 10-bushel or better crop were 84 in 100.

When little or no rainfall occurs soon after seeding in soil moist to a depth of only a few inches, the probability of failure is greatly increased. When the initial soil moisture is deficient and the precipitation is low to April 1, it is probable that abandonment of the crop and the conservation of water in a summer fallow for a future crop will pay far better than allowing the water to be wasted by the poor crop and the weeds on the land.

Much of the hazard of winter-wheat production in the central Great Plains can be avoided by limiting the acreage in years when wheat must be planted on soil that is not wet to an adequate depth. In some sections a summer fallow for an entire season may be necessary to store the necessary quantity of water, and in sections with heavier precipitation cultivation beginning immediately after harvest may be sufficient in most seasons. In particularly dry seasons no method of cultivation may be able to provide the necessary protection.

Fifteen varieties of oats, developed by breeding mostly in cooperation with the Iowa, New York, Oregon, and Idaho Agricultural Experiment Stations, were distributed from 1913 to 1931. These improved varieties are now grown on 10,000,000 to 15,000,000 acres annually. Among these varieties Richland and Iogold are highly resistant to stem rust, and Markton is extremely resistant to smut. These varieties have been crossed with others resistant to crown rust, and certain of the hybrid selections from the crosses are resistant to all three diseases and in addition are very promising in yield.

Eleven corn hybrids developed in cooperation with the Iowa, Illinois, and Indiana Agricultural Experiment Stations were distributed during the period from 1932 to 1934, inclusive, and were grown on nearly 115,000 acres in 1935. Each of these hybrids has yielded an average of 12 to 26 percent more than good local varieties in comparative tests during the last 4 or 5 years. These hybrids also have been much more resistant to lodging than the open-pollinated varieties with which they have been compared.

Experiments with newly developed early maturing varieties, such as Sooner milo, indicate that they may be planted as late as July 1 or 15 in most of the commercial grain sorghum producing areas and still

mature a crop of grain. For late planting, certain of these newly developed varieties are far superior to the ordinary varieties that are more productive when planted early. Sooner milo has matured and yielded satisfactorily as far north as South Dakota, and also under irrigation at Logan, Utah, in the intermountain region.

The root-rot disease attacking milo and darso has been found to be caused by the organism known as *Pythium arrhenomanes* Drechs. This organism occurs in the soil of many localities and attacks corn and sugarcane and certain varieties of sorghum. This disease can be controlled by the use of resistant varieties. Resistant strains of milo have been selected by the Kansas Agricultural Experiment Station in connection with cooperative studies of the disease. Susceptibility to the disease is inherited in a simple genetic manner.

The "white-tip" disease of rice has been demonstrated to be caused by an iron deficiency. The disease is characterized by a loss of chlorophyll from the leaf tips and by chlorotic spots in older leaves. Plants severely affected have dwarfed, twisted culms and twisted leaves and panicles, a condition that results in a marked reduction in yield. Some varieties are less susceptible than others. In greenhouse experiments the deficiency of iron, which is associated with an alkaline soil condition, was corrected by applications of calcium cyanide, sulphur dust, or ammonium sulphate.

Grass and Pasture

Ecological studies in the central and southern Great Plains to determine the effect of heat and drought on native grasses were made at eight different stations in this region in cooperation with the Kansas Agricultural Experiment Station, and the Division of Dry Land Agriculture, and the Soil Conservation Service of the Department. Buffalo grass and blue grama constituted more than 90 percent of the total vegetation on all soils except those which were very sandy. Buffalo grass was more abundant than any other grass on the heavier soils, but blue grama was found to be adapted to a much wider range of soils. A large percentage of the native grasses were killed during the drought in 1933–34. Soil blowing and overgrazing contributed materially to the damage, but heat and drought caused much more injury than grazing. As the intensity of grazing was increased the actual ground cover of buffalo grass decreased. Heavy grazing and drought caused more injury to blue grama than to buffalo grass. Pastures were severely injured by the drought but surviving plants remained evenly distributed so that with favorable climatic conditions and proper management recovery to normal stands should be possible in a few years.

Woolly fingergrass introduced from South Africa was grazed for the first time at Tifton, Ga., in comparison with other grasses. This grass, planted vegetatively in 1934 on unfertilized Tifton sandy loam soil and with an incomplete stand, carried for 216 days three head of steers with an initial average weight of 443.3 pounds. The average gain per steer was 340.3 pounds or a daily average gain of 1.58 pounds per head. This was the largest daily gain on any grass pasture at Tifton, and these steers were in better condition than any others. Comparable steers on a pasture of carpet grass, Dallis grass,

lespedeza, and white clover fertilized annually with 600 pounds per acre of complete fertilizer made an average daily gain of 1.40 pounds per head. Bermuda grass and lespedeza produced an average daily gain of 1.02 pounds per head, and kudzu was the only type of pasture at Tifton on which the daily gains of the steers exceeded those of the woolly fingergrass pasture, the average for kudzu being 1.60 pounds. The introduction of woolly fingergrass has revived hopes of providing productive pasture on poor upland soils of the Cotton Belt. It is both palatable and nutritious but, unfortunately, has failed thus far to produce viable seed. Breeding designed to overcome this weakness was begun this year.

During the past year, three new lettuce varieties or strains have been released to the seed trade. One of these varieties released to seedsmen under the designation Columbia No. 1 is a crisp heading sort similar in appearance to the New York and is adapted to culture in the eastern part of the United States. It appears to be resistant to tipburn and better adapted to eastern conditions than any strain of the New York type of lettuce previously grown. Another variety is a midseason or summer crop, one adapted to the Salinas-Watsonville section in California and designated as Imperial 847. It appears to be brown blight-resistant. The third variety of the group is a mildew-resistant strain of the Grand Rapids variety for greenhouse culture. It has been released under the name Grand Rapids No. 1.

Fertilizer Placement

In cooperative tests having to do with the placement of fertilizer in the soil with reference to the position of the tobacco plant, striking results were obtained with respect to both the survival of transplants and the final growth and quality of the crop. Perhaps the most critical period in growing the tobacco crop is that immediately following transplanting, a good stand and a quick, even start in growth being highly important. Certain placements of the fertilizer resulted in a high mortality of plants, so that although the crop was replanted two to four times perfect stands were never obtained and the growth of the surviving plants was irregular. Side placements have produced uniformly good results, whereas mixing the fertilizer in the band of soil from 4 to 6 inches in width and depth around the plant gave poor results. When the fertilizer was placed in a band underneath the plant, the results were unsatisfactory. Where the fertilizer was drilled in the open furrow and stirred with the soil and the row then ridged, the results as a rule were good, although they did not equal those obtained with the side placements. Split applications of fertilizer, with a portion applied to the side, usually produced the highest yield and value of crop obtained in the tests. In comparative tests with standard-strength and high-analysis mixtures, the results obtained were in close agreement.

On some of the principal cotton-producing soils of the Southeast the reinforcing of fertilizers with magnesium and calcium neutralizing agents has rendered fertilizers more effective in the growing of cotton. When fertilizers are made nonacid-forming, the less costly soluble organic and inorganic sources of nitrogen may be as efficient on many cotton soils as the more expensive natural insoluble

organic sources of nitrogen and all the fertilizer may be applied at or in advance of planting on many soils without serious danger of loss by leaching. The application of such fertilizers at planting tends to reduce the production cost of cotton when compared with the system of applying the mixture containing part of the nitrogen at planting and the remainder as a separate application after the crop is up. Fundamental work with machine placements of fertilizers to cotton, in cooperation with the Bureau of Agricultural Engineering, has shown side placements to be the most satisfactory. Efforts are being directed toward devising practical and inexpensive means of accomplishing this placement of fertilizer.

WILDLIFE

WITH allotments from emergency funds aggregating $8,500,000, the Bureau of Biological Survey on July 1, 1934, undertook the task of averting the most serious crisis with which waterfowl in this country have ever been faced. Of this amount, $8,100,000 has been expended, and the balance has reverted to the Treasury.

The most protracted drought in our history, drainage operations, and attempts to reclaim land for agricultural purposes had combined to bring about an extremely serious shortage of waterfowl breeding, resting, feeding, and wintering grounds. This condition, augmented by an increase in botulism and other waterfowl diseases, large-scale hunting activities, and the toll taken by predatory animals had so alarmingly reduced the waterfowl population as to forecast extinction of many species within the space of the next 5 years unless preventive steps were taken at once.

To save waterfowl and restore them to approximately their former abundance was and is the primary consideration of the Survey's activities, but it should not be overlooked that these activities constitute a powerful weapon in the battle toward economic recovery and reconstruction. This will be evident from consideration of the following integral parts of the duck-restoration program:

1. Purchasing large areas of submarginal land, which in practically every case has proved entirely unfit for agricultural usages. The sale of their land has enabled distressed farmers to move to more desirable locations and start anew.

2. Employment by the Survey of a large number of men, many of whom were on relief rolls. This is especially important, since, in the main, these activities are located in drought-stricken areas that have been the hardest hit by the depression.

3. The construction of storage dams, marsh embankments, and other water-impoundment devices in the course of the development of practically every wildlife refuge. These improvements will conserve valuable water resources which are now being dissipated to an alarming degree. The drought has emphasized the need for the conservation of water, and the popularity of the Survey's activities in the Dakotas, for example, shows that there is great public interest in this phase of conservation.

4. The propagation and protection of heavy growths of vegetation for waterfowl food and cover. Such work forms an important part

of the refuge-development program and helps to repair the damage which the uncontrolled action of wind and water has inflicted.

Between $800,000.000 and $1,000,000,000 is spent annually for sportsmen's equipment and outdoor facilities, and a million people depend wholly or in part upon some aspect of this business for their livelihood. In addition, there is the fur industry, with an estimated $500,000,000 annual turn-over in retail trade. The threat to industries of such proportions obviously merits attention.

The educational and esthetic value of wildlife is important, and laboratory facilities are being provided on a number of the waterfowl refuges. The fund of data in the natural sciences will thus be enriched. The hunting, as well as the observation, of waterfowl furnishes millions with healthful recreation. On many wildlife refuges the Survey is developing picnic grounds and bathing facilities for the use of the public.

The total acreage of bird-refuge land actually administered by the Biological Survey as of February 29, 1936, exclusive of the acreage of those refuges located in Alaska, Hawaii, and Puerto Rico, and exclusive also of a large acreage of big-game land on which birds are also protected, is 2,118,433 acres and includes more than 100 refuges. There are additional areas on which options for purchase have been approved by the Migratory Bird Conservation Commission. These areas total some 999,398 acres and include 36 areas that are now, or soon will be, functioning as waterfowl refuges through special permits from the owners. Thus it may be said that there are now under the Bureau's jurisdiction over 3,000,000 acres of bird-refuge land.

Big-Game Refuges

Two outstanding big-game refuge projects have been inaugurated under the $6,000,000 appropriation approved June 15, 1935. One of these provides for the enlargement of the Elk Refuge in Teton County, near Jackson, Wyo., to take care of the great bulk of the elk of the southern Yellowstone herd which winter in the Jackson Hole country. This project involves the acquisition of 20,000 acres to be administered in connection with the 4,500 acres already owned and operated at that point. Roughly, the area includes the land lying north of Jackson, east of the Jackson-Moran Highway, south of the Gros Ventre River, and west of the boundaries of the Teton National Forest. The elimination of private interests from this area and the restoration of grazing therein will provide an abundance of winter feed for the elk. This project is very important.

The other project is known as the Hart Mountain Antelope Range, in Lake County, southeastern Oregon. It has been established by Executive order in connection with the organization of grazing districts under the Taylor Act. The purchase of some 25,000 acres of privately owned lands has been initiated under the 1935 appropriation above mentioned.

Other pending projects for the designation of ancestral game ranges have been agreed upon in connection with the grazing districts being organized under the Taylor Act.

Improvement of big-game refuges by C. C. C. camps has continued at the National Bison Range, Mont.; the Niobrara Game Preserve,

Nebr.; the Charles Sheldon Antelope Refuge, Nev.; and the Wichita Mountains Wildlife Refuge, Okla.

Federal authority over migratory birds will be reinforced and extended by an act of Congress approved June 20 to give effect to the convention between the United States and Mexico for the protection of migratory birds and game mammals. The United States Senate on April 30 consented to the ratification of the treaty. Mexico has not yet ratified the treaty. It will take effect on the exchange of ratifications. Federal authority over migratory birds has heretofore depended on the Migratory Bird Treaty with Great Britain. The new treaty reinforces this authority by providing for a dual basis for the Federal regulations conserving ducks, geese, and other migrants.

With the signing of an agreement by State agencies in Ohio, nine States are now cooperating with the Biological Survey in investigations to learn how to increase, maintain, and use wildlife resources and to show on trial areas how research results can be applied. The cooperating States are Alabama, Connecticut, Iowa, Maine, Ohio, Oregon, Texas, Utah, and Virginia. These were selected for research on a regional basis and to avoid duplication of effort. Each State program is arranged so that the information obtained may be applied in a large area.

AGRICULTURAL ENGINEERING

The best regulation and use of the waters of at least 11 of the Western States depend upon reliable forecasts of stream flow. Advance knowledge of stream flow is indispensable to the proper operation of irrigation, hydroelectric, and flood-protection works. In the making of such forecasts, however, adequate snow surveys are necessary, and snow surveying has not yet reached the required proportions. Accordingly, the Bureau of Agricultural Engineering, in cooperation with other Federal and State agencies, is planning several hundred new snow courses for survey during the winter of 1936–37. This undertaking will extend the snow-survey work into areas not now served.

This Bureau has had the responsibility of coordinating, standardizing, and extending the snow-survey work of various agencies. It issued forecasts of the 1936 season's water supply for the greater parts of California, Oregon, Nevada, Idaho, Utah, Wyoming, and Colorado shortly after April 1936. These forecasts indicated that most of the streams would yield 100 to 125 percent of the normal supply and that the run-off would equal the highest recorded in the last 10 years. With this assurance, irrigators prepared to plant all the area that had heretofore been irrigated.

However, the unusually warm spring resulted in a very early and very heavy run-off. In areas having inadequate storage facilities much water ran to waste; and in some areas little irrigation water was left for late-season needs. Warned against planting late crops, farmers adjusted their cropping programs and avoided certain loss. Where long snow-survey records were available, it was possible to distribute the water among the storage reservoirs in such manner as to effect the greatest economy in its utilization.

The net safe yield of water for irrigation from western watersheds depends upon reservoir storage. Evaporation from lakes and reservoirs results, however, in a material loss. This loss is largely unavoidable, but knowledge of its magnitude and of the factors that influence evaporation helps in devising means for reducing the loss, in estimating the available reservoir supply, and in determining the feasibility of reservoir-construction projects. It is useful also in planning irrigation, municipal water supply, and hydroelectric projects. The data collected by the Bureau provide the basis for estimating the evaporation losses from the surfaces of stored water and from water transported long distances in open conduits.

The best use of water requires an understanding of soil characteristics, particularly those related to the absorption and retention of water. Studies of the rate of movement of capillary moisture have high practical value in determining soil-moisture conditions, with or without irrigation. Studies of the infiltration of water into the soil indicate what types of soils can best be irrigated, and how land should be prepared for irrigation. Research in the Bureau of Agricultural Engineering is throwing new light on these problems.

Irrigation to protect high-value crops against drought is receiving increased attention in the Eastern States. Where sufficient water can be had at reasonable cost, the practice is profitable in growing fruits and vegetables. In the spring of 1936 irrigated strawberries on the Eastern Shore in Maryland produced an excellent crop of high-grade berries. The increased income this year practically paid the cost of installing the irrigation equipment. Adjacent unirrigated fields, because of drought, produced no marketable berries. Profitable results from irrigating fruits and vegetables were reported also from Florida, Michigan, New Jersey, Ohio, Virginia, and West Virginia. But results from the irrigation of general field crops in the East do not as a rule justify the expense.

Common tillage practices in the production of cotton can readily be modified so as to increase the yield and lower the cost of production on at least one soil type—Greenville sandy loam. This has been discovered in tillage experiments carried on for 5 years at Prattville, Ala. The methods and the tools used in tillage influence both fiber length and yield. Operations repeated each year with implements that improve or injure the soil structure have a cumulative effect on the crop. The depth and the method of turning under green manure crops also influence the yield of cotton on this soil.

Improved Farm Equipment

New or improved equipment is being put out by farm-machinery manufacturers partly as a result of investigations by Department engineers. This machinery includes (1) fertilizer distributors that place the fertilizer, during the planting operation, at the proper distance to the side and below the seed to be of greatest benefit to the crop; (2) the variable-depth cotton planter, which eliminates the necessity for replanting except under extraordinarily unfavorable weather conditions; and (3) a basin-forming attachment for the lister when used in planting corn, designed to form dams at short

intervals in the lister furrows to conserve moisture by holding rainfall and to prevent or reduce erosion by water and by wind.

Farm-machinery sales have increased. Information received by the Bureau of Agricultural Engineering indicates that the value of all the equipment sold in the United States by manufacturers in 1935 was $325,566,909, as compared with $248,979,523 in 1931. Sales during 1936 will probably exceed $400,000,000. Much of the increase will be due to the sale of newer types of equipment, such as the general-purpose tractor on pneumatic tires, and the small combined harvester-thresher. It is estimated that no fewer than 7,500 combines operated from the tractor by power take-off and mounted on pneumatic tires were used this year in the Corn Belt and the Southern States. These machines harvest a variety of crops satisfactorily, particularly soybeans and small grain. The power take-off, which of course does away with the need for an engine on the combine, reduces the cost of the machine greatly; and the pneumatic tires make lighter construction possible. Though the small machines have a narrower cut than the machines formerly in common use, the rate of harvesting is not proportionately lower, because the smaller machines can be pulled at higher speeds.

Tests conducted at the Department's cotton-ginning laboratory at Stoneville, Miss., have attracted wide interest. Many ginners are modernizing their gins and following the recommended methods. In the 1935–36 ginning season 200 seed-cotton driers, built on a principle patented by Department engineers, conditioned about one-third of a million bales of damp cotton for ginning. About 300 such driers may be in operation in the 1936–37 ginning season.

In buildings for the storage of fruits and vegetables in commercial quantities, especially in cold climates, the control of temperature and humidity (or air-conditioning) is important not only for the safe and economical holding of the crop but for the prevention of damage to the buildings. Investigations of potato storage by this Department in cooperation with the Maine Agricultural Experiment Station have developed an improved method of obtaining the desired air conditions. These methods take advantage of the well-known fact that moist air coming in contact with a cold surface deposits moisture, and in so doing liberates about 1,000 British thermal units of heat per pound of moisture condensed. In this way the walls of the storage house are dampproofed and the ceiling is insulated more than the walls, so that high humidities to aid in keeping the potatoes in good condition can be held without damage to the building. In cold weather excess moisture given off by the potatoes is drained away as water, with much less loss of heat from the building than if it were carried away as vapor by ventilation. Heating and ventilation during cold weather are reduced to the minimum and loss of weight by the potatoes is lessened. The same principle is applicable to the storage of other vegetables and fruits. With some modification it may be useful in buildings for livestock and for other purposes.

Improvement of Farm Homes

The improvement of farm homes remains one of the unaccomplished tasks of agriculture. Observations in many parts of the country indi-

cate that comparatively few farm families have as yet found it practicable to provide themselves with modern homes either through new construction or by modernizing the old dwellings. Sooner or later there must be a tremendous volume of farm-home improvement and new construction. Therefore this Department, in cooperation with the State Universities of Wisconsin and Georgia, is gathering facts about the comfort and service provided by various types of farmhouses found in the North and in the South. One phase of the investigation deals especially with the factors in house design that contribute to comfort in hot weather. The results should aid materially in the development of improved designs.

GRADING AND STANDARDIZATION

A NEW principle entered the grading and standardization work of the Department this year. It was the use of the referendum to decide whether or not a group should have mandatory inspection based on Federal standards for market quality and condition.

This new development was provided for in the Tobacco Inspection Act, signed in August 1935. Permissive inspection, which began in 1929, has demonstrated the feasibility and practical value of tobacco inspection based on standard grades. Several referenda indicated that tobacco growers in large numbers want mandatory inspection. They see in it a means of reducing the costs and improving the efficiency of marketing and distribution.

The tobacco-inspection service has for its object the certification of the grade on each lot of tobacco offered for sale at auction. It is designed to overcome the average producer's lack of technical knowledge of the qualities and values of his tobacco and to improve the general technique of marketing the crop. It is coupled with a price-reporting service that gives the current average prices for the various grades. These two services enable the grower to have, at the time he sells his tobacco, a competent and disinterested judgment on the quality and approximate market value of his offering.

As a result of favorable votes in several referenda, mandatory inspection service has been ordered for 18 tobacco markets, and another market has voted favorably on the matter and will soon be designated. The law, however, has been challenged in the courts, and a temporary injunction issued, which for the time being stops the grading of tobacco on three designated markets in South Carolina.

The first official inspection service known to have been provided for any agricultural commodity was a tobacco-inspection service. It was passed by the Virginia House of Burgesses in 1619. Since then much legislation pertaining to tobacco inspection and to other phases of production and commerce in tobacco has been enacted. However, the Tobacco-Inspection Act is the first piece of national legislation providing for tobacco inspection that has had for its primary object the protection of the producer's rights and interests when he offers his tobacco for sale. The first State legislation of a similar character was enacted by Virginia in 1933. It related to fire-cured tobacco, type 21, which is produced in a group of counties south of the James River.

An educational program has been started in connection with the mandatory tobacco inspection and the market-news service to promote improved methods of sorting tobacco and preparing it for market. This program is limited at present, but it has met with an encouraging response from county agents, agricultural teachers, farmers, and the tobacco trade.

Permissive Federal Standards

There has been for many years an extensive use of Federal standards on a purely permissive basis. Along with the use of mandatory Federal standards for cotton and grain under certain interstate marketing conditions, the voluntary use of optional Federal standards has developed. Progress has been particularly noteworthy in the fruit and vegetable industry. Ten years ago the Federal Inspection Service inspected 198,075 cars. Last year it inspected 395,250 cars. In the concurrent development of the two methods the compulsory and voluntary use of Federal standards have promoted each other. This year marks the first meeting of compulsory and voluntary action in the case of a single commodity.

Extensively revised standards were recently promulgated for grain and cotton to meet the needs of changing production and marketing practices and to embody new knowledge.

The United States standards for cotton also serve as the universal standards for American cotton. Accordingly representatives of nine principal European organizations were consulted in the revision of the standards. Leading representatives of American organizations of producers, manufacturers, and shippers were consulted also. The revised standards became effective in August 1936. They are more representative than the former standards of the characteristics of the cotton now produced and are more readily used. The number of grades is reduced from 37 to 32, and the number of standard boxes from 25 to 13.

Along with the whole question of what constitutes quality in cotton, methods are being studied for the further measurement of quality. New techniques are being devised and tested. They may permit further improvement in the standards.

The revised grain standards were drawn to meet changes in merchandizing, milling, other processing, and baking. All groups interested in grain marketing from the farm to the export wharf were urged to examine and test the revised standards before they were promulgated. Somewhat less significant, but not less useful, revisions are being made in the permissive standards from time to time.

Farm products inevitably include wide ranges in quality. Standards must change with significant changes in production practices. Sometimes preferences and requirements of consumers vary decidedly in different markets. Changes in industrial technique or in methods of marketing may change the importance of certain quality factors or quality standards. New knowledge of nutritive values may upset previously formulated specifications of desirability, and new techniques for the measurements of quality may make improvements possible. It is, therefore, necessary to revise the standards periodically.

Improvements in Standardization

The first Federal standards were largely empirical, but in expert hands they served. As a basis for transactions between distant points, for a common trade language between farmers, dealers, and consumers, for market quotations, for price and market comparisons, and for agricultural financing and credit, they answered many vital wants. But research and experimentation in the Department steadily improved the standards and the methods of applying them. Methods, instruments, and other apparatus were adapted to specific ends. Many public-service patents have been obtained for apparatus designed especially for grain standardization and inspection, and for other agricultural commodities. This year saw the conclusion of an exhaustive practical test of a new grain-sieving device known as the Federal dockage tester, the making of new conversion charts for use with electric meters in determining the moisture content of Argentine flint corn and several other grains, and an improved refractometric method for determining the oil content of flaxseed. This method requires only a half hour instead of the 16 to 24 hours formerly required. In commodity grading much still remains subject to human judgment and skill, particularly in regard to such factors as flavor, body, and color in butter. But accurate measurements, through mechanical or chemical means, are steadily replacing the earlier empirical knowledge and ways.

These techniques are the results of laboratory and economic research supplemented by practical observation. The studies are frequently intricate but the resulting tests must be simple and practical. As a general rule, the standards reflect the normal spreads in the market value of a commodity. The steps between grades correlate fairly closely with the price differentials that prevail in the market. Research is providing more precise measures of the price significance of separate quality factors. Some quality factors that affect prices, however, may not yield to statistical measurements, and it is necessary then to rely on observation and judgment.

The relationship between the grades and market price differentials does not remain constant necessarily. Price spreads between grades of a product frequently reflect the proportions of the product that fall within each of the grades. There are other influences. Buyers' opinions as to value do not always correspond to intrinsic value. Before the Federal standards were adopted, for instance, "pea-green color" was the quality factor in alfalfa hay that commanded a premium. Research disclosed that the feed value of alfalfa hay correlates more closely with its leafiness. Then the factor of leafiness was given greater emphasis in the standards. Steadily increasing premiums paid for leafy as compared with pea-green alfalfa apparently reflect the influence of the revised standards. Present studies give special consideration to the carotene or provitamin content of hay.

Naturally, standards have limitations. They cannot meet all requirements. Some believe they are too general, and do not adequately measure variations in quality. This difficulty often lies in the products. As research yields more accurate measures of quality factors, the descriptive standards will become more precise.

Sometimes the margin recognized between the upper and lower limits of some grades may seem to be too wide and may not adequately reflect qualities peculiar to the products of various regions. But the national grades have to serve the national industry. It is impracticable to narrow them so as to cover all gradations in quality. Regional characteristics that have market value may be covered in additional local notations. It may prove desirable for some commodities to have different sets of standards for different stages in marketing. Special consumer grades may sometimes be practicable for retail use.

Consumer Interest Awakened

In fact, an outstanding recent development has been the awakening of consumer interest in commodity standardization. Led by informed and organized groups, the consumers' voice increasingly demands grade specifications that can be used in making household purchases, and truthful and informative labeling based on these grades. Consumers have a right to know what they are buying. The Federal standards for meat are adapted to consumer needs, and the Federal labeling of meats by grade has had excellent consumer response. Beginning in 1927, in the first full year of this service, 28,000,000 pounds of meat were officially graded and stamped. During the last fiscal year 423,000,000 pounds were so graded and stamped. Originally only beef was stamped; now beef, lamb, mutton, sausage, and certain other meat products are included. Seattle in 1934 passed an ordinance requiring that all beef, lamb, and mutton sold within the city limits be graded and stamped. Schenectady, N. Y., has passed a similar ordinance.

The labeling of canned fruits and vegetables according to grade has made rapid progress. The movement has strong consumer support, and strong support among certain groups in the canning trade. One large chain-store organization is using Federal grade designations on its pack of several fruits and vegetables and giving them national distribution. National advertisers, however, are reluctant to adopt uniform grade labeling. They fear that their brands will lose prestige. But brands do not give consumers the information they want. There is no reason, moreover, why both the brand name and the grade designation cannot be used on labels. The Federal standards for butter, eggs, and certain kinds of poultry are suitable for consumer use. Labels based on these grades are coming into retail use.

Possibly the next line of decisive progress will be in the greater use of Federal grades by consumers. That may require the development of special grade specifications or descriptions.

HOME ECONOMICS

Letters that pour into the Bureau of Home Economics indicate that the American public has turned "consumer conscious." Men as well as women are asking daily for help in planning budgets. They want to know how to get the most for their money, no matter how adequate or how limited their income. The economic situation of recent years has made families at all levels of living conscious of the need to budget their resources, to buy wisely, and to save. This

is true of heads of families and of single men and women whose letters indicate a good educational background, but it is equally true of those whose letters indicate that their educational opportunities have been meager. It is true of families who are trying to adjust to the budgeting of incomes of $5,000 to $6,000 a year when they formerly were distributing very much larger amounts for family needs, and also true of families who are trying to make ends meet when the total resources consist of less than $60 a month from work relief.

The solution of such problems must come in part through study of the spending habits of American families. Yet there has never been a comprehensive study of American consumption habits and needs. For this reason the Bureau of Home Economics is now cooperating in such a study, which has been launched under the Works Progress Administration.

When the Emergency Relief Appropriation Act of 1935 was passed proposals to undertake a study of consumption habits as a Federal Works project were submitted jointly by the National Resources Committee, the Bureau of Home Economics, and the Bureau of Labor Statistics, the latter Bureaus constituting the administrative agencies. The study of consumer purchases was approved by the Works Progress Administration in December 1935. Methods for collecting, editing, and tabulating the necessary data were developed cooperatively by the Bureau of Home Economics, the Bureau of Labor Statistics, the National Resources Committee, the Central Statistical Board, and the Works Progress Administration.

The work of selecting a staff and of setting up regional and local offices in 27 States was begun in a preliminary way in January 1936. The field work, begun shortly thereafter, is now nearing completion, and statistical pools are engaged in tabulating the data. Information has been collected from about 50,000 families interested in cooperating to the extent of giving facts about their income, about the age and occupation of their members, and about the commodities and services they buy. About half of these families have given more detailed information on their expenditures for housing, food, clothing, transportation, medical care, and various other types of goods and services, and on their savings. In addition, from a smaller number of families, detailed information has been obtained on the kinds and quantities of food, household equipment, furnishings, and clothing procured.

Families living on farms, in villages, and in small city areas are cooperating with the Bureau of Home Economics. City families are cooperating with the Bureau of Labor Statistics. When all of the facts are consolidated we shall know for the first time what typical American families actually buy and what kind of living they get.

The cooperating families represent different occupations and family incomes ranging from $250 up to $5,000 or more a year. The facts will typify living conditions in different sections and will show variations due to rural and city living.

Not only will the families profit who assist in the study but the findings will be valuable to all families who want guidance in budgeting. Consumers' wants should eventually be met more satisfactorily because the information, when summarized and interpreted,

will help farmers and manufacturers to produce with less waste. Merchants will have a better guide to probable changes in consumer demand. The United States Chamber of Commerce requested such a guide a few years ago.

The social value of the study will be important. The public, and local, State, and Federal agencies concerned with public health and general welfare, will have new facts to show the prevailing levels of living in this country and to indicate the need for betterment.

Value of Diet Statistics

Facts about what the public eats are indispensable in planning farm production and distribution. Such facts also have an important bearing on education in dietary problems. The general well-being of a people is largely dependent on the adequacy of their diet. Many families who now fail to get a satisfactory diet can have a satisfactory diet for the same expenditure if they will consider both nutritive value and cost in choosing their foods. In order to help them the Bureau of Home Economics prepared Farmers' Bulletin 1757, Diets to Fit the Family Income. This bulletin discusses scientific principles of nutrition and food economics in nontechnical language.

During the past year, the Bureau analyzed the kinds and quantities of food purchased and the nutritive value of the diets of wage-earning families. The necessary records were collected by the Bureau of Labor Statistics, in conjunction with a study of the disbursements of families of wage earners and low-salaried clerical workers. About 2,500 records became available for this analysis. As a result, extensive figures will soon be available on the kinds and quantities of food purchased by city wage-earner families in different sections of the country at different seasons of the year, and at different levels of expenditure.

The diets have been analyzed for their nutritive content and appraised in the light of dietary standards. A preliminary report of the work appeared in the July 1936 issue of the Monthly Labor Review. This report, with an analysis of the diets of nonfarm American families as shown by studies made during the last 20 years, was sent to the International Labour Office and to the health committee of the League of Nations in December 1935.

The quantity of all food purchased (on a per-capita basis) increases, as one would expect, with the expenditure for food. This was shown by classifying into groups the diets of all families studied, by $32 intervals adjusted to 1935 price levels. From a level of expense for food of $32 to $65 per capita per year to a level of expense for food of $258 to $290 per capita per year, the increase in weight of food per capita as shown by this classification was almost threefold. Naturally, however, the percentage increase from one level to another was much greater at the lower than at the upper levels of expenditure.

For some food groups, such as the grain products, purchases increase relatively little as expenditures increase. Foods from the cereal grains usually are cheap in relation to their ability to assuage hunger. Hence, they appear, as might be expected, in generous amounts in low-cost diets. as well as in expensive diets. The con-

sumption of milk increases rapidly with increasing expenditures at the lower levels, but less rapidly after the pint-a-day level of consumption is reached.

With increasing expenditure for food, changes in the quantities consumed of fruits and vegetables (other than potatoes and dried legumes) are very striking. The increase from the lowest to the highest level of expenditure is almost sixfold. Citrus fruits, tomatoes, and leafy, green, and yellow vegetables comprise about 40 percent of the total in each level of expenditure for food. These fruits and vegetables are mentioned especially because of their significance as sources of vitamins and minerals.

The increase in the consumption of lean meats and fish is almost threefold between the lowest and highest levels of expenditure, while the consumption of fatty foods almost doubles. Butter consumption increases almost five times, but the consumption of other fatty foods remains almost constant. Butter seems to be used in addition to and not as a substitute for lard, bacon, salt pork, and other fats and oils.

The fourth of the nonfarm population that spends the most for food consumes about one-third of the milk, fruits, vegetables (other than potatoes and dried legumes), meat, fish, and eggs, whereas the fourth that spends the least for food consumes about one-sixth of those products. Differences in consumption at different economic levels in any one region are much more important than differences between geographical regions at any one level.

Social Implications of the Data

The most frequent level of expenditure for food among the families from whom dietary records have been taken was found to be that ranging from $100 to $130 per capita per year (1935 price levels). About half of the families were spending less than $130 per capita per year. According to 1935 prices, a minimum-cost adequate diet could be obtained with careful food selections for just about $130 per capita per year. The inference is that the diet of half the nonfarm population probably fails to provide a desirable margin of safety over minimum requirements. At the lowest levels of expenditure for food the calorie intake is far below the average for the population and far below the probable need; one need not, therefore, be surprised to find retarded growth in children and undernutrition in adults.

On the other hand, the figures shown for families spending the larger amounts for food probably represent quantities available to the household rather than quantities actually eaten. They include considerable household waste. Hence the quality of the diets of the higher-income groups depends on how much and what is wasted. Calorie for calorie, the food supply purchased by families spending the largest amounts for food is only slightly higher in proteins, minerals, and vitamins than the diets of low-income groups. But if the milk and vegetables and fruits purchased are almost completely consumed, while waste occurs principally in the fats, sugars, and grain products, the food actually eaten by the higher-income groups may be considerably richer in minerals and vitamins than the diets of low-income groups.

138904°—37——8

The percentage of the calories purchased in the form of grain products is much higher in low-income groups than in the higher income groups; it ranges from more than 40 percent in the lowest level of food expense studied to somewhat less than 30 percent of the calories at the highest level. An opposite trend may be observed for most other groups of foods. The percentage of calories derived from milk almost doubles as the expenditures for food increases, and the percentage derived from lean meats, fish, and eggs increases significantly.

Futher study of these consumer purchases will furnish more authoritative figures on food-consumption habits and on food expenditures. It will show, for example, how food-consumption habits may vary among families spending the same amounts for food, but representing different socioeconomic groups. It will also provide figures on the proportion of the native-white families of each type that represent different levels of food expenditures.

There is widespread interest in these data, not only from the standpoint of science and social welfare but also from the standpoint of the economic implications. The governments of many nations, as well as international and national bodies of economists, educators, and others interested in social and economic planning, are giving much attention to these problems.

COMMODITY EXCHANGE ADMINISTRATION

To improve and protect the means furnished by properly conducted futures-contract markets for the hedging of price risks by growers, dealers, and processors of essential agricultural products, the Grain Futures Act of 1922 was strengthened by amendment on June 15, 1936. It was extended to cover cotton, rice, millfeeds, butter, eggs, and potatoes, and the short title changed to the Commodity Exchange Act.

The principal amendments include the following:

That commission merchants and brokers executing orders for customers in a contract market shall register with the Department of Agriculture and shall keep adequate accounts and records, which shall be available for official inspection; that copies of all bylaws, rules, and regulations adopted by contract markets shall be filed with the Secretary of Agriculture and their books and records be made available for inspection; that operators of warehouses from which any commodity is made deliverable on futures contracts shall keep such records, make such reports, and permit such visitation as the Secretary of Agriculture shall require; that when so directed by the Secretary, each contract market shall provide for a period, after trading for future delivery in any delivery month has ceased, in which to make settlement by delivery, such period to be not less than 3 or more than 10 business days; that each such market shall require the party making delivery to furnish the party receiving delivery written notice of the date of delivery at least 1 day prior thereto; that deliverable commodity grades must conform to United States standards, if such standards shall have been officially promulgated; that receipts of federally licensed warehouses, as such, shall not be discriminated against in deliveries upon futures contracts.

Provisions of importance to cooperatives are that no contract market shall forbid the payment of patronage dividends by a cooperative association to bona-fide members; that a properly qualified cooperative association shall not be excluded from membership in and trading privileges on a contract market unless such exclusion is authorized after notice and hearing before the Commodity Exchange Commission, except for failure to meet its obligations with the clearinghouse of the exchange; and that cooperative associations of the federated type are authorized to compensate on a commodity-unit basis their regional member associations for services rendered, provided such compensation is distributed as a dividend on capital stock or as a patronage dividend out of net earnings or surplus of the federated association.

Special protection has been thrown around the margin moneys of the customers of futures commission firms. The act requires all futures commission merchants to treat and deal with all margin moneys, including securities and property, as belonging to customers. Such funds must be separately accounted for and may not be commingled with the funds of the commission merchant or used to margin the trades or contracts or extend the credit of any person other than the one for whom the same are held.

The danger of excessive trading by individuals or allied groups is also given special attention. The Commodity Exchange Commission has wide discretion in fixing limits for speculative trading whenever it appears that such limits are necessary. Ample latitude for hedging is carefully preserved.

Fraudulent trading is made more hazardous. Criminal penalties may be imposed for various offenses, such as conducting a bucket shop, speculative trading in excess of a limit fixed for such transactions, the manipulation of prices, engaging as a futures commission merchant or floor broker without prior registration, trading against customers' orders, dealing in privileges, making wash sales and cross trades, and fictitious trading.

During the past year three cases pending under the Grain Futures Act of 1922 were dismissed following decision of the Circuit Court of Appeals of the Seventh Circuit that the law did not apply to past offenses. This defect in the original law has been remedied in the amended act, which provides penalties for any person who has violated the act as well as for any person who is violating the act.

COOPERATIVE EXTENSION WORK

The cooperative agricultural extension system operates in two principal fields of service: (1) It mobilizes Federal, State, and county facilities for helping farm people to solve their ordinary problems of production and marketing, homemaking, and country-life improvement. (2) In great national emergencies it tackles the resulting special problems. In the last few years it has taken an active part in the administration of production-adjustment programs: loans to farmers on stored crops; drought-relief measures; programs for the prevention of soil erosion; programs for debt adjustment and farm-credit improvement; and rural rehabilitation and relief.

In advancing these programs and activities the extension agents directly represented the Federal and State agencies. They acted as advisers and assistants in the organization and educational work, and functioned also in an administrative capacity in cooperation with local committeemen and producers' groups or associations. The county extension offices were the centers where committeemen and extension agents gave practical help and necessary instructions.

Local committeemen assisted capably in the administration of the national programs, particularly in dealing with regulations, rulings, agreements, papers, and essential forms. They relieved extension agents of much detail work and enabled them to handle more efficiently their larger responsibilities. In many counties local committeemen handled most of the local routine involved in the national programs.

Both paid agents and volunteer leaders furthered the educational features of the extension programs. Without the help of local volunteer leaders the rural boys' and girls' 4-H club work would have suffered. Local leaders helped also to conduct adult demonstrations and rural educational meetings. As a result farmers are coming to understand better how general economic conditions affect their individual problems. They discuss the effects of tariffs, quotas, price policies, price levels, currency measures, monetary systems, credit, taxation, and land-use policies. They are learning more about the interdependence of town and country and about the limitations of individual self-sufficiency. They are grasping the logic of group action in meeting emergencies. That agriculture is constantly changing and needs to make constant readjustments is now a potent conception in the rehabilitation of rural life.

The Extension Service aided farmers to take advantage of the agricultural conservation program inaugurated this year and to adopt other soil-improvement practices. It encouraged them to put land in better shape by seeding legumes for hay and for soil improvement, by sowing or treating pastures, by terracing, by planting cover crops, by strip farming, by listing, by building soil-saving dams. Such work is going forward on a scale never approached before.

When drought became serious this year the Extension Service aided farmers in growing emergency crops and in making the best use of the feed available. Temporary silos were built by the thousands. Feed-supply surveys were made and feed supplies budgeted. Exchange lists of feed were distributed. Feeds and emergency fodders were brought in from nondrought areas and distributed through central agencies.

Extension agents and local leaders cooperated with the regional agency set-up for clearing feed supplies. They helped farmers in pooling their orders so that they might obtain reduced freight rates. They helped farmers to make applications for crop-production loans and feed and seed loans. In cooperation with the Agricultural Adjustment Administration, the Extension Service conducted Statewide corn-fodder and feed-conservation campaigns. Water sources were tapped.

Combating Insect Plagues

Extension agents facilitated Federal and local cooperation in combating insect plagues. Thus in Illinois county agents were notified on June 8 that creosote would be made available by the Federal Government for building barriers against chinch bugs. At 9:30 the following morning orders for this Federal creosote were placed with the Federal purchasing agent. In all, 1,281,800 gallons were allotted to the 60 counties of the State where this pest threatened to do the most damage. About 10,000 miles of chinch-bug barrier were constructed in Illinois with the Federal creosote.

In areas affected by the drought, the consequences of which will be felt for years, the Extension Service is seeking with the aid of technical advisers to determine what the future farming program should be. It will encourage farmers to reorganize their cropping systems and to initiate different soil practices wherever the conditions of soil and climate warrant that course.

The farmers who have suffered are anxious for sound programs for both long- and short-time needs. They want the facts from which they may develop programs suited to their needs. The Extension Service recognizes the resulting responsibility. With recovery, and with time released from emergency projects, extension workers will not simply go back merely to old lines of work. New and larger problems demand attention, involving economic and social relationships as well as production factors. This calls for coordinated research and planning.

Accordingly, extension agents and research agencies are pushing a county agricultural planning project. After meetings with farm groups in every county it is hoped to develop recommendations for adjusting farm operations in terms of (1) national and international economic influences, (2) rational land use, and (3) farm management. Such recommendations should serve to develop county programs of the greatest significance.

City dwellers commonly think of farm life as synonymous with good food and health. Yet in some rural sections the problem of nutrition is acute. In certain areas some groups of farm people actually suffer from a lack of essential foods, though most of these foods could be produced there. The drought and the depression made this situation worse. Therefore the Extension Service gave more impetus to campaigns for growing and preserving food for home use, and the campaigns met with an extremely favorable response. County extension agents estimated in 1935 that the value of the food canned or preserved on farms in that year was $18,875,090. Home-produced vegetables, milk, eggs, meat, and fruit now appear on the table of many a farm where formerly the idea prevailed that the purpose of a farm was merely to produce crops for sale. The farmer who makes a living on the farm will have that living and some cash besides. When drought and depression strike, the family's living is surer and better.

The relief load was lightened, too, by the work done to produce food for home consumption in industrial centers. Thousands of gardens brightened mine settlements and industrial towns and helped to provide needed wholesome food. In one Eastern State the home-

garden and food-preservation movement required the services of about 125 garden supervisors and 175 canning supervisors. Four and a half million pounds of produce was grown in these gardens. More than a million cans of high-quality vegetables were prepared for distribution by welfare boards last winter.

Methods of Reducing Living Costs

Extension programs developed to aid people in lowering costs of living were popular. In fact, extension work with farm families was marked by constant adaptation to the problem of lowered family incomes, unemployment, relief, and social welfare. Encouragement and instruction were given in producing handicraft articles and other things for sale. Making, remodeling, and repairing garments were taught.

Drought and depression and recovery have forced farm people generally to recognize the needs of a profoundly changing country life. They will continue to want help and direction in adjusting themselves to these changes. By study and planning, many things may be averted or their bad effects modified. By planning and acting in cooperation with the community, the State, and the Nation, farmers may make recovery more lasting. It is the task of the Extension Service to furnish the information and the organizational help necessary to accomplish this result.

COOPERATIVE RESEARCH PROJECTS

Federal and State agencies cooperated in new and extended lines of agricultural research during the year, and improved their organization for greater service to agriculture and the general public. As usual the State agricultural experiment stations worked closely with other State agencies, with local organized groups, with each other in regional groups, and with this Department individually and in regional and national groups in efforts to plan and coordinate research. Cooperative research thus fostered dealt not only with the adjustment and relief policies of the National and the State Governments, but with permanent policies of agricultural production, land use, and rural life. The Office of Experiment Stations examined and recorded 818 new or revised formal cooperative agreements between bureaus of this Department and the experiment stations. The agreements covered 731 major research undertakings. All the State experiment stations and all but one of the Department's research bureaus participated. There were also many informal cooperative agreements, some of them of major importance.

Certain regional and national cooperative research undertakings which had been started on an emergency basis as parts of the national recovery program in 1934 and 1935 were modified and expanded to meet more permanent requirements. These studies brought more closely together the parallel interests of plant- and soil-science research and those of crop- and animal-production research with more thorough consideration of their economic and social influences. Studies of adjustments in farming by regions and type-of-farming areas from the standpoint of national agricultural adjustment received considerable attention in this connection and were

typical of the renewed and expanded efforts in cooperative research. In this case, a review of similar work done the previous year indicated the need for more complete studies.

A general plan for further action was agreed upon by State and Federal representatives at the meeting of the Association of Land-Grant Colleges and Universities in the fall of 1935, and formed the basis of widely extended cooperative research in regional adjustment policies in 1936. Nearly all of the States cooperated in this important study. This Department contributed to the work primarily through the Bureau of Agricultural Economics, but also through the Agricultural Adjustment Administration, the Soil Conservation Service, and the Forest Service. Among the State experiment stations it was common to find from 5 to 10 subject-matter departments actively engaged in coordinating their studies so as to fit both State needs and the national adjustment study program.

Another significant development in cooperative research during the year was the adoption of a policy for establishing and operating regional research laboratories under the Bankhead-Jones Act of June 29, 1935. Following negotiations with the land-grant colleges and the State experiment stations this Department issued a statement of policy on December 19, 1935, which embodied suggestions from its bureaus and recommendations from the State stations approved by the executive body of the Association of Land-Grant Colleges and Universities. Among other things, the statement of policy provided, as a basis for the activities of the regional laboratories, that the Secretary of Agriculture will receive suggestions from the experiment station directors and from bureau chiefs in this Department; that he will locate such laboratories solely with regard to the technical requirements and the facilities available; and that the Department and the State experiment stations will enter into memoranda of understanding regarding the work to be done, the cost of doing it, the sources of the funds, and the coordination of the laboratory research with regular activities of the States and the Department. Federal and State specialists will cooperate in preparing detailed plans.

Three Regional Laboratories Approved

In accordance with this policy three regional laboratories were approved during the last fiscal year; one for research in vegetable breeding; one for soybean research, with particular reference to the industrial uses of soybeans; and one for the study of grass breeding and pasture improvement. In the agreement covering the soybean laboratory, which is typical, 2 bureaus of this Department and 12 State experiment stations participated. It provides for integration of research at the laboratory with research at the experiment stations in the region and for the revision and reformulation annually of the research program.

The study during the year of grain storage on the farm is typical of the cooperative research into broadly important regional or national problems, initiated under the provision in the Bankhead-Jones Act for research by this Department other than at regional laboratories. In this undertaking, three of the Department's bureaus and seven of the State experiment stations, together with several other organized

Sate groups, cooperated in a manner which brought to bear on the problem the correlated knowledge and training of several different specialists. Besides avoiding duplication of effort, the arrangement avoided unnecessary duplication of research equipment.

Before the fiscal year ended, officials of this Department and a majority of the directors of the State experiment stations adopted a memorandum of understanding covering research relationships between the Soil Conservation Service and the stations. It recognized that effective cooperation in research by these agencies is primarily dependent on working to a common end, rather than on financing, and that each agency should contribute what it can in experience, knowledge, and personnel. It was agreed that such research as may be mutually agreed on with reference to soil erosion and its prevention requires mutual helpfulness, if it is to be fully effective. Accordingly, the memorandum provided that details of cooperative research projects within a State shall be planned and executed jointly by the State experiment station and the Soil Conservation Service. This understanding has far-reaching significance because it recognizes not only the need of regional policies in erosion control but also the limitation of action by individual States and Federal bureaus.

Federal and State agencies cooperated during the fiscal year in a national survey of plant and animal improvement. This provided the basis for material published in the Yearbook of Agriculture for 1936 regarding the character and availability of superior germ plasm in 19 plants and animals, and preliminary material for subsequent work on other animals and plants. This cooperative study brought together in a usable form the available information on animal and plant genetics and exercised a favorable influence on the further planning of similar studies.

As part of an enlarged Federal-State program in the study of land utilization, land-use adjustment, and soil conservation the inventory of soil resources was expanded to include 30 States. In six other States the work was completed. The widespread cooperative efforts in crop improvement were continued and expanded. Typical of these were the forage-crop investigations which were extended to include 11 States; the work in 5 States was completed. Other similar, widely cooperative researches were the breeding and improvement of grasses, corn, and potatoes.

Important New Cooperative Studies

Cooperative studies on other agricultural problems included several important new undertakings, among them a study of milk marketing in New England, the development of a program of agricultural economics in New England, studies of tobacco and cotton diseases, an evaluation of meat investigations, and a master study on human nutrition.

At a conference in November 1935, sponsored by the directors of the interested experiment stations, plant pathologists engaged in tobacco disease investigations in the southern tobacco-growing States formed a permanent organization known as the Tobacco Disease Council. This council laid plans for a coordinated attack on particular problems by special groups composed of experiment station and Department specialists and including representation from a privately endowed uni-

versity. A second conference, in June 1936, reviewed progress, took steps toward further voluntary coordination and cooperation along specific lines, extended the movement to more northern tobacco areas, and united it with the efforts of specialists on insect pests.

A similar conference, initiated by experiment station specialists with the cooperation of specialists of this Department on diseases of cotton, resulted likewise in the organization in February 1936 of a cotton disease council, with parallel objectives. As a result several serious disease problems of the Cotton Belt were taken up cooperatively by experiment station and Department specialists.

Food and nutrition specialists of several of the middle western experiment stations formulated a regional cooperative program of research on the nutritional status of college women. There is accumulating evidence of a relatively widespread chronic undernutrition among young women of college age. An executive committee has been appointed by experiment station directors to guide the work. The cooperation of the medical staffs of departments of hygiene and physiology has been enlisted.

FOOD AND DRUGS LAW ENFORCED

Artificially flavored and colored beverages which simulate genuine fruit products are frequently found to be in violation of the Federal Food and Drugs Act. Artificially colored, acidulated, and otherwise camouflaged products masquerading as bona-fide fruit beverages cannot fail to reduce the utilization and consumption of fruit. Operation of the Food and Drugs Act caused one manufacturer of an orange-oil-flavored beverage to change his formula to conform to the label, which indicated the presence of fruit juice. He began, in consequence, to purchase annually about 1,000,000 gallons of orange juice. This required some 10,000 tons of oranges. Previously the only orange product used in his beverage was orange oil.

In the spring of 1935 it became evident that maple sugar and sirup were occasionally contaminated heavily with lead. The contamination was traced to the use of sap buckets coated with lead alloy, and steps were taken to obviate this threat to health. But large stocks of the contaminated product were on hand. Investigations in this Department have suggested a simple procedure for the elimination of the poisonous contaminant. If this is successful, these stocks can be salvaged, and it will be unnecessary to divert thousands of gallons of the sirup and thousands of pounds of the sugar from food use, with consequent heavy loss to the producers.

One of the problems always before food and drugs law enforcement officials is that of the decomposition of foods. Procedures for the better preservation of perishable commodities and methods for the detection of unsound products, either in their raw state or as ingredients of food compounds, are very necessary. Research in the Food and Drug Administration constantly improves the technique. The application of various methods of analysis specially developed by the chemist, the bacteriologist, and the microscopist, to detect unwholesomeness in foods, not only results in the necessary condemnation and destruction of spoiled products, but frequently suggests better methods of handling and storage.

The study of vitamins has practical applications in food and drug enforcement. More than 4,500,000 gallons of cod-liver oil were used in this country last year, of which approximately 95 percent was imported. There are no statistics of the respective proportions used for human consumption and animal feeding, but it has been estimated that more than half of this oil is used for animal feeding, mostly for poultry. Cod-liver oil added to poultry feeds yields profits under efficient poultry management. When there is a lack of sunshine it supplies the necessary vitamin D to obtain maximum growth and egg production.

Surveys of the vitamin D content of the cod-liver oils used in poultry feeds revealed that a surprisingly large proportion fall below the required standard for vitamin D. Some of the oils are practically worthless. Examinations of a number of importations indicated that a significant portion of the imported oils are deficient in vitamin D. Cod-liver oils are now being examined for their vitamin content before their entry is permitted. The detention of shipments pending vitamin assays means inconvenience and expense to importers, but it is the only way to assure the users that the product is of satisfactory quality.

Livestock and Poultry Remedies

Of particular interest to farmers is enforcement of the Food and Drugs Act with respect to livestock and poultry remedies. Annually many of these are found to be worthless. During the past year the Federal courts in three contested cases upheld the Government's action against a contagious abortion remedy composed of cornstarch with a trace of potassium permanganate, which was sold for from $5 to $12 a pound; a protection powder labeled as a preventive for almost all the diseases of livestock and poultry, which consisted essentially of Glauber's salt and baking soda, sold at $7.50 per hundred pounds; a poultry remedy composed of water, alcohol, carbolic acid, and potassium chlorate, at 75 cents per quart, labeled an effective treatment for all poultry diseases.

Enforcement of the Food and Drugs Act on these veterinary preparations prevents serious losses to farmers. The price paid for the fake remedies is not the only thing involved. More serious is the fact that reliance on ineffective drugs delays the application of the proper treatment and sacrifices animals that might be saved.

ROAD CONSTRUCTION

Road construction administered by the Department during the year included work on the main through highways, the construction of secondary roads reaching into farming areas, extensions of the main system into and through municipalities, the improvement of roads in Federal areas, and the elimination of railroad-highway grade crossings.

A total of 27,373 miles of highways, roads, and trails, and 310 grade-crossing structures were brought to completion during the year. Of this mileage, 22,133 was improved with Federal funds administered solely by the Department. The remainder consisted of 204 miles of national-park roads built for the National Park Service by the Bureau of Public Roads; 2,319 miles of loan-and-grant projects of the Public Works Administration, also supervised by the Bureau of Public

Roads; and 2,718 miles in work-relief projects, the labor on which was supplied by the Federal Emergency Relief Administration. Other costs connected with these projects were paid with Public Works funds, and supervision was furnished by the Bureau of Public Roads and several State highway departments.

The major activity of the Department in road construction consisted of the administration of funds provided as direct grants to the States for relief of unemployment through highway and grade-crossing work and as Federal aid to the States for highway purposes. The work was carried on cooperatively with the various State highway departments in accordance with the general plan of administration of Federal aid for highways, but modified to meet the need of giving employment to those on relief rolls.

Work of this kind resulted in the completion during the year of 13,789 miles of roads and streets—7,355 miles on the Federal-aid highway system outside of cities, 755 miles on city extensions of the Federal-aid system, and 5,679 miles of secondary or feeder roads. On these classes of highways combined there were completed 310 railroad-highway grade-separation structures. Also completed were improvements on 22 miles of flood-damaged highways, on 236 miles of forest highways, and on 436 miles of highways through other public lands built by the Bureau of Public Roads, and 5,684 miles of forest roads and 1,965 miles of trails built by the Forest Service.

The current program at the end of the year involved a total of 25,812 miles in all classes of projects. It comprised 10,006 miles on the Federal-aid system outside of cities, 991 miles on city extensions of the system, 7,921 miles of secondary or feeder roads, 716 miles of forest highways, 261 miles of public-lands highways, 537 miles of national-park highways, 2,478 miles of loan-and-grant projects, and 2,902 miles of work-relief roads, the last three supervised by the Bureau of Public Roads as agent for other Federal departments. The current program also included 1,664 structures separating the grades between railroads and highways.

Railroad Grade Crossings

Authorization of $200,000,000 to eliminate danger at railroad-highway crossings under the Emergency Relief Appropriation Act of April 8, 1935, enabled the Department, for the first time, to participate in such work on a large scale with funds not subject to other demands for highway improvement. It has included in the program many urgently needed improvements not undertaken before because of hesitancy to spend large amounts of highway funds on a few structures. Approximately 2,000 crossings are to be eliminated with the new funds. Nearly 7,000 grade crossings have been eliminated with Federal assistance since 1916, but comparison with this figure does not give a fair picture of the value of the new work, because many of the new projects are of exceptional importance.

The work of the last year resulted in the elimination of 300 grade crossings either by structures or by relocation of the highway, the reconstruction of 10 existing structures, and the installation of protective devices at 185 additional crossings. Work under contract and approved at the end of the year will increase the number of grade

eliminations by 1,466 and the number of protected crossings by 813.

The total employment for the year on work supervised by the Bureau of Public Roads was 1,673,935 man-months, or the equivalent of an average full-time employment each month of 139,500 men. The number of individuals actually employed, some of them on a part-time basis, averaged approximately 195,000 persons per month. Indirect employment in the production and transportation of equipment and materials is estimated at one and six-tenths times the direct employment for work of the character done during the year. This resulted in an indirect employment of 2,678,000 man-months, and this, added to the direct employment, gives a full-time employment of 4,352,000 man-months, the equivalent of the full-time continuous employment of 362,000 men.

Secondary or Feeder Roads

Secondary or feeder roads have been receiving increasing attention from the Department. Actual participation in the construction of such roads began in 1933; 15,037 miles of secondary roads have been completed. Improvement of these roads is now a fixed policy of the Department. The general demand for better farm-service roads is reflected in the trend toward placing local roads under the control of State highway departments.

State and Federal highway officials must now plan for the improvement of secondary roads while they continue to make needed improvements on the main highways and to carry on work in still another new direction—the improvement of main routes through and around cities. Highway administrators face a difficult situation if they attempt to plan for these different classes of work on the basis of the incomplete knowledge now available. Serious mistakes and set-backs to highway development can be avoided only by knowing the amount of each class of improvement that is economically and socially justified and what will be the annual cost of needed improvements. Plans must be based on a thorough study of highway revenues, the sources from which they come, and the fairness with which taxes for highways are imposed.

Recognizing the need for highway planning on a businesslike basis, the Department has invited all of the State highway departments to participate in State-wide highway-planning surveys to be financed with 1½ percent of certain Federal highway funds and under specific legislative authority for the making of surveys and investigations for future work.

At the close of the fiscal year 40 States had indicated their desire to carry on planning surveys, and work was under way in 31 States. In these surveys data are being collected as to the highway mileage and its present condition of improvement, the extent to which each road is used, the extent to which various classes of residents use the different classes of roads, and the amount of taxes they pay for road purposes.

It is believed that the surveys will result in the assembly of facts necessary to the formulating of a definite, economically, and socially defensible, integrated highway-improvement program.

Henry A. Wallace,

IN SENDING *out to the public this second and last of the two yearbooks on genetics and breeding, I would not want anyone to think that they complete the account of the efforts of plant and animal breeders in the United States. On the contrary, I would wish these yearbooks to be looked on as pointing the way toward a field of activity that will accomplish much more in the future than has been accomplished in the past. Life is always changing because environment is always changing. There are always new types of diseases, new insect pests, changes in soil fertility, changes in consumer demands. The work of the plant and animal breeders is directed to meeting these changes. It has only just begun. We have reached our present stage of development largely by rule-of-thumb methods; but discoveries not dreamed of a few years ago are being made, and they counsel greater boldness in experiment and promise closer control because they give us an increased understanding of the processes that go on in the minute cells where life has its beginning.*

If genetics enables us to outdo nature's own efforts, it is because it is in the truest sense a science of cooperation with nature. We want to do different things than nature does—for example, in the creation of hogs with plump hams or wheat×grass hybrids with plump seeds—but we have to learn nature's methods of doing them. I think that more knowledge of how to cooperate with nature for our own good is the greatest need of the world today. Man's control of his own future may depend in the long run on whether his biological knowledge, which is constructive, can catch up with his knowledge of the physical sciences, which has taught him so much about how to destroy.

HENRY A. WALLACE.

WHAT THE BOOK IS ABOUT

GOVE HAMBIDGE, Principal Research Writer, Office of the Secretary

THIS book rounds out the work of the committee on genetics appointed by the Secretary of Agriculture in 1933. The task set for the members of the committee was to make a national and to some extent an international survey of practical breeding and genetic research with those plants and animals that are important in American farming. The first fruits of the work appeared in the 1936 Yearbook of Agriculture as a series of papers dealing chiefly with the major crop plants and classes of livestock. The present volume covers an enormous and varied field, dealing with garden vegetables, northern tree and bush fruits, subtropical fruits, flowers, nut trees, forest trees, forage grasses and legumes, Angora and milk goats, turkeys, ducks, fur-bearing animals, honeybees, and finally that good friend of the farmer, his dog.

Many of the articles are unique in that nothing of a similar kind has been done in their field, and the two yearbooks together probably contain the most complete and up-to-date account of breeding work and genetic research in relation to farm plants and animals that can be found gathered in one place. Even in those cases where there is little work of a really scientific nature to report—and this is true in some instances, for scientific breeding is by no means universally applied as yet—the writer of the article has explored possibilities and endeavored to foresee fruitful lines of effort. Indeed, the possibilities of the future are necessarily a theme that runs through both books, because this science of genetics is relatively young, and much as it has accomplished in creating new forms of life better suited to the needs of man than the old, its greatest achievements undoubtedly lie ahead.

The genetics yearbooks, it may be said frankly, have something of the hybrid nature of much of the material with which they deal. They are intended for two groups: (1) Readers who want to know what is going on in the field of plant and animal breeding in order to enlarge their understanding and to enable them to carry on their farming operations more intelligently, and (2) students and others who have, or expect to have, a closer concern with the science of genetics. The latter group comprises scores of thousands of individuals, including young people now in schools and colleges who will be the American farmers and the agricultural scientists of tomorrow—some of them future leaders in shaping agricultural progress; a large number of workers in various parts of the country who are engaged in the practical effort to create better plants and animals; and teachers, extension workers, and others whose business it is to know as much as possible about all the major factors in modern agriculture.

To combine the interests of these diverse groups in a single volume is a difficult task, but judging from the generous reception given the last Yearbook, the results have at least been characterized by a certain hybrid vigor.

Another purpose also underlies this survey of breeding and genetics. It is an attempt to make a frank appraisal of the present situation on a major segment of the agricultural front—not only to sum up achievements, but to expose weaknesses and shortcomings. The reader of the 1936 and 1937 Yearbooks will admit that the shortcomings have not been neglected. In almost every case, it is shown that we are far short of attaining the objectives that scientists believe we may attain with means as potent as genetics. As a matter of fact, though systematic breeding with such major crops as wheat has been going on for some time and has shown splendid results, it has only been begun in the last few years with many of the crops treated in the present book, and it has not had time to show what it can do. In other cases, the work is necessarily so slow that the results of the very earliest systematic efforts are only now beginning to be used. In the case of a new apple variety, for example, it takes nearly 40 years from the time the cross is made to the time when the variety is actually in commercial production. Tree breeders live in the present but think in the future.

On the positive side, however, there have been such outstanding achievements as the development of the wilt-resistant Marglobe tomato, which is now widely grown and saved the Florida producers from ruin; strains of cantaloups resistant to powdery mildew and of lettuce resistant to brown blight and powdery mildew—both of vital importance to California growers; snap beans resistant to some of the chief diseases that plague producers; cabbages resistant to yellows; sweet corn of such uniform and superior quality that it has remade canning practices; superior varieties of raspberries; blueberries far better than those produced by nature; a large number of improved navel oranges from bud selections; and many interesting new fruits created by hybridizing different kinds of citrus. Some of the new varieties and strains of plants developed by this constant activity are not yet quite ready for introduction.

Thus it is both heartening to discover how much has been accomplished and humbling to realize how little we know. There is probably not one writer of these articles who does not feel that the effort to sum up the past achievements and present status of the work in his field has been worth while. It has forced him to find out where we stand, to make a critical examination of what has been done, and to bring together many scattered fragments, so that their significance can be seen in the whole picture, including their relationship to the work of others in different fields. It would be well if a similar audit or stock taking could be made in other major branches of agricultural science, and, in fact, such a plan is now projected in the Department.

Much of the material was collected, as in 1936, through cooperative survey forms, or questionnaires, designed to survey the breeding and research work in all State agricultural experiment stations and in similar public institutions abroad. Private or endowed institutions, and even individuals, were included sometimes when it seemed that

they might have valuable data. The information reported from institutions in the United States and Canada was in general considerably more detailed and complete than that from overseas, but in the latter case there was not always sufficient time to prepare complete data. A great deal of work was required in filling out some of these survey forms, and the Department heartily thanks all who cooperated.

The preparation of the papers was assigned to Department scientists actively specializing in work with each kind or group of plants or animals. The authors have drawn on their own experience and knowledge, and on the whole field of technical literature, as well as summarizing the information obtained from the cooperative survey of plant and animal improvement. The only uniform rule adopted for the papers was that the material of most interest to the intelligent farmer or the general reader was to come first and to be put in language as nontechnical as possible. The more strictly technical material was placed last. Thus, after the principle successfully followed by Jack Spratt and his wife, the general reader may skip the brief technical section at the end of most of the articles if he wishes, and the technical reader may skip the first part of the article if he is so inclined. Basic data and tables, including lists of plants with superior germ plasm for various characteristics available for future breeding work, appear in appendices to the articles.

Though the genetic background and breeding techniques are essentially the same with a good many different plants, it will be found that some discussion of these aspects of the work has been repeated to a certain extent. Since each such discussion is related to a particular organism, however, it seemed best to let the repetition stand, partly for the benefit of readers who may be interested only in certain articles. Moreover, the subjects dealt with in the present book will appeal to a large number of gardeners, orchardists, beekeepers, and other enthusiasts or specialists who may have only vague notions about genetics, even when they carry on practical breeding with the plants or animals in which they are most keenly interested. In such instances a certain amount of repetition should be useful in making the basic facts understandable.

Four articles in the last part of the book—which some readers may prefer to read first—deal in greater detail with some of these fundamentals. The science of genetics is not a particularly easy subject, though its broad principles are not difficult to grasp, and anyone who wishes to go very far in plant or animal breeding must be prepared to undergo some mental discipline in the study of theory and technique if he expects to get all the facts straight. But for that matter, the details of the radio are not easy to grasp, either, yet there are thousands of capable radio amateurs who know a good deal about them. And in breeding work there is the advantage that the techniques involved, and the facts of genetics as far as they go, are at least relatively definite, which is more than can be said, for example, of the technique of writing good prose or poetry.

These concluding articles have been written with the lay reader in mind, but it will be found that they cannot be skimmed over like a detective story. On the contrary, they need to be read with the close attention that the detective in real life would give to some rather

138904°—37——9

difficult technical evidence. For one of these articles we are indebted to A. F. Blakeslee, of the Carnegie Institution of Washington, who has been doing extraordinary things with the chromosomes of *Datura*, the genus to which our common jimsonweed belongs. Research in the field of unusual chromosome numbers is now attracting a good deal of attention among practical breeders because it suggests unique methods of creating new varieties and even new species of plants—that is, methods that are unique insofar as man is concerned, though it would seem that nature has used them from the beginning. For the chronology of genetics we are indebted to Robert Cook, editor of the Journal of Heredity, and to many of the leading geneticists and breeders in the United States, who critically examined his manuscript. E. N. Bressman has undertaken the difficult task of explaining some of the theory on which modern breeding practices rest; and J. R. Magness has dealt with the differences between vegetative reproduction and reproduction by seeds, which must be clearly understood in breeding work.

For a glossary of genetic terms the reader is referred to the 1936 Yearbook of Agriculture.

SUMMARY OF YEARBOOK ARTICLES

In the following pages all of the articles in the 1937 Yearbook are briefly summarized so that the general reader may quickly grasp the scope of the work as a whole.

Vegetable Crops—Introduction

In comparison with such major farm crops as the cereal, fiber, sugar, and forage plants, the vegetable crops are far more numerous, less understood genetically, and usually more limited to regional or national use. For example, superb English varieties of peas or cucumbers, or Italian varieties of tomatoes, either do not do well in this country or do not suit our habits and prejudices. In some countries Amercian sweet corn is not considered fit for human food; and on the other hand, many vegetables commonly eaten in Asia are unknown in the United States. Vegetable breeding, in other words, is a highly localized affair. We draw on the whole world for variant plant forms, obtained by the Division of Plant Exploration and Introduction in the Bureau of Plant Industry, but today these are used almost entirely as sources of genes for specific characteristics needed to strengthen and improve our own favorite types.

Systematic vegetable breeding by public agencies in this country is for the most part not more than 10 or 15 years old— in some cases, very much newer. Prior to that time, for decades and generations individuals and commercial firms had been busy producing better vegetables, largely by mass selection, with a little hybridizing here and there. Naturally, we owe most of our present varieties to the work of these men. The number of improved new forms introduced by public agencies is as yet very small, though in acreage they make a more respectable total. They will steadily increase. The kinds of problems that are pressing today, notably the urgent one of disease resistance, and the increasing complexity of the research needed for quicker and more certain results make the old haphazard methods

obsolete, excellent as they were in their time, and necessitate a well-organized scientific attack by public institutions. The commercial agencies in turn benefit by the work of these institutions. Seed certification in itself, though not directly connected with breeding, has been a State function of great value in holding the advances made by breeders.

Two new Federal institutions are of unusual interest and potential value. One is the United States Regional Vegetable Breeding Laboratory just established at Charleston, S. C., under the authority of the Bankhead-Jones Act of 1935. This is the only station in the United States devoted exclusively to vegetable breeding, and it will be concerned with basic problems affecting the Southeast. The other is the Great Plains Horticultural Field Station at Cheyenne, Wyo., where everything possible will be done to extend the meager list of vegetables now available for growing under the trying conditions found in this region.

There is a single appendix for most of the articles on vegetable breeding in the Yearbook, and this appendix includes work being done with some crops—sweetpotatoes and peanuts, for example—on which there was too little material to warrant separate articles.

Tomatoes, Peppers, Eggplant

As in the case of some of our literature and other native American products, Europe appreciated the tomato first, while Americans did not generally know that it was good to eat until about 1850, and the first improved varieties came from England and France. After 1870, commercial breeders in this country were active in selecting chance variants characterized by large handsome fruits, high yield, and plants adapted to local conditions. Among the leaders in this work was A. W. Livingston, of Columbus, Ohio. He and his associates were geniuses at selecting and perpetuating superior tomatoes. By 1910 there was a rich range of varieties, and the old methods are still used with some good results.

Chance variation is not certain enough, however, to meet the pressure of modern needs for resistance to disease, heat, and cold, and adaptability to long-distance shipment, new areas of cultivation, new processes and uses. Since 1910, there has been a more systematic attack on these problems by State and Federal workers, and a greater use of genetic analysis and controlled hybridization to meet them. Major attention has been given to resistance to fusarium wilt, but nailhead rust, leaf spot, leaf-mold, mosaic, and curly top have all had some attention. Practically speaking, no research agency today would introduce a new tomato unless it was resistant to at least one very troublesome disease.

Many State stations have done and are doing notable work in this field, and the list of new varieties is growing to respectable length. Federal workers have also been very active. The most important variety of tomato in the world today, Marglobe, was developed by Pritchard and Porte in the Department. Marglobe is highly resistant to wilt under most conditions and to nailhead under all conditions, and it came in time to save the Florida tomato-shipping industry from ruin. But Marglobe has faults too, and it will be superseded by

better tomatoes that will develop from the active research and experiment now going on.

Hot and sweet peppers, or chilis, also are native to tropical America. There has been comparatively little breeding work with these plants, and all the types grown today were known 200 or 300 years ago. A few enthusiasts among private breeders, however, have made improvements, particularly in uniformity, conformity to type, thickness of flesh, and earliness of maturity. The New Mexico and the Louisiana stations have introduced improved strains of hot peppers, and the Massachusetts and Connecticut stations have introduced early sweet peppers adapted to New England.

Even less systematic breeding work has been done with eggplant because of the relative unimportance of this crop in the United States. Native to the Tropics of the Old World, it has long been esteemed in some of the oriental countries. All the important varieties grown here were developed by private gardeners and seedsmen. The New Hampshire, Rhode Island, and Wisconsin stations are doing some breeding work for increased earliness, and the Central Experimental Farms of Canada have introduced an early productive strain of Black Beauty

A rather impressive amount of research has been done on the genetics of the tomato, but there is a great need for the development of more accurate tests to measure degrees of resistance to disease as a foundation for working out the inheritance of resistance. More basic information of this kind is needed if practical breeding is to achieve results with greater certainty. Of great theoretical interest is the newer work on forms with abnormal chromosome numbers—both triploids and tetraploids have been produced artificially There has been much less genetic and cytological research with the pepper and the eggplant In the case of the eggplant, Japanese workers have made some interesting studies of hybrid vigor and parthenocarpic fruiting (without fertilization of the ovules).

Cucurbits

Cucumbers and muskmelons are believed to have come originally from India and watermelons from tropical Africa. Pumpkins and squashes are of American origin. Columbus thoughtfully brought muskmelon seeds to North America, and in a few years native tribes from the West Indies as far north as Canada were growing melons. The early commercial and private breeders did their job so well with all these crops that some varieties originated over a hundred years ago are still popular among growers. Indeed, improvement by breeding today centers largely on fighting disease and spreading the climatic range of some of the cucurbits.

Cucumber growers suffer heavy losses from mosaic, downy mildew, and bacterial wilt. In the search for resistant varieties, plant breeders of the Department of Agriculture have found promising material among stocks from the Orient—China, Japan, India. Inbred lines of these show considerable resistance to mosaic and some resistance to mildew and wilt. Work is now in progress to introduce resistance into otherwise good American varieties by hybridization. At the Maine station, cucumber scab has received attention, and inbred

lines pure for resistance, as determined by artificial inoculation, have apparently been found.

The story of the development of our numerous melon varieties from material drawn from many parts of the world is a complicated and interesting one. The most striking work in disease resistance has been in connection with powdery mildew, which suddenly became a menace in the Imperial Valley, the chief muskmelon section of the United States, in 1925. By 1928 J. T. Rosa of the California station and I. C. Jagger of the Department of Agriculture had discovered resistant plants in material from India. Commercially useless, they were crossed with good American varieties, then backcrossed to the American parent variety to improve quality, and a resistant hybrid, of which Hale Best is one parent, was ready for use by 1932. Further backcrossing to Hale Best and 2 years more of selection brought the still better Powdery Mildew Resistant Cantaloup No. 45 in 1936. The mildew threat in this area has been beaten. Resistant strains of Honey Dew and Honey Ball are now being developed.

The California station has recently developed superior watermelons from the old Klondike and Stone Mountain, and from Russian stock the Minnesota station has bred a watermelon that can be grown farther north than others. The most serious watermelon disease is fusarium wilt. Within the last few years, the Iowa station has bred a number of resistant strains, and in 1936 both the Florida and the California stations released new wilt-resistant watermelons. It is interesting to note that the first recorded attempt to synthesize a commercial plant resistant to a particular disease was a hybrid between watermelon and stock citron (wilt-resistant but inedible), made by Orton of the Department of Agriculture and produced in 1911.

Squash breeding has had rather different objectives—the production of varieties superior in uniformity, earliness, quality, and appearance. This has been done chiefly by isolating superior lines among varieties rich in variable characteristics—a task that is facilitated by the fact that inbreeding generally has no harmful effect on cucurbits (and, conversely, crossing apparently does not result in hybrid vigor). The Vermont station has been a leader in this work. The North Dakota station has produced a squash of high quality in an attempt to create a substitute for sweetpotatoes in the northern Great Plains area. The California station and the Connecticut station at New Haven have recently introduced new squashes.

Some inheritance studies have been made with all the cucurbits, and interesting work has been done on reproductive responses, breeding behavior, and pollination technique, in all of which there are peculiarities not common to other plants.

Onions

The Israelites wandering in the wilderness complained bitterly to Moses because they had no onions. The unique, pungent flavor of onions makes them in no less universal demand today. Americans consume well over a billion pounds a year, worth $17,000,000 to growers—not counting the onion relatives, garlic, leeks, shallots, and chives.

Varieties have a rather strict regional adaptability partly because they refuse to produce 100 percent normal bulbs except with a certain definite length of daylight. One group will do this with a short day of 12 hours. Another requires a 13-hour day, and another 13½ hours. Yellow Globe Danvers demands 14¼ hours of daylight, and Sweet Spanish strain no. 2 still more. Extra-early varieties, like Bermudas, will not do well when seeded in the North because the day has already passed the minimum bulbing length by the time seed is sown. Late varieties will not do well in the South because when the day is the right length for bulbing, heat, sunscald, pink root, and thrips retard growth. These conditions can be changed when breeders develop varieties resistant to diseases and insects and adaptable to a wider range of climatic conditions.

The principal troubles of onions are pink root, smut, mildew, smudge, neckrot, yellow dwarf, thrips, and bolting (premature seeding). Until recently, there was little or no attempt to overcome these troubles by breeding. Today the prospects look very promising. One of the most valuable aids in breeding for resistance to various troubles may prove to be the Japanese onion, especially the Nebuka type. Nebuka onions belong to a different species than our onions, and they are of very little use commercially in the United States because they produce no bulbs. But they are resistant to various diseases, insects, and adverse climatic conditions, and by suitable crosses, these qualities can be transferred to American types.

Active work is in progress now in the breeding of hybrids with Japanese onions that are resistant to thrips, pink root, and smut. Work is also in progress in isolating strains of onions resistant to mildew. Resistance to smudge, it has been determined, is due to a certain acid associated with the pigment in yellow and red bulbs; whether the genes responsible for this acid can be incorporated into white onions remains to be seen. A substance in the outer scales of colored bulbs also seems to be poisonous to the fungi that cause neckrot. The Sweet Spanish variety of onion has been found to be very resistant to the virus disease, yellow dwarf. Resistance to thrips shown by certain varieties and species seems to be due to growth habits and leaf shapes that fail to offer protection to the insects; perhaps there are also other characters involved that help the plants to withstand injury. Certain varieties have been found to be highly nonbolting, and these are being crossed to produce nonbolting hybrids. Indications are that the same thing may be done to secure resistance to freezing injury.

With such facts determined, the breeder is in a position to carry on a well-directed program. Techniques of inbreeding and cross-breeding are well developed. The onion is normally cross-fertilized, and selfing results in rapid deterioration, but with care it produces pure strains for hybridization. In making difficult species crosses—as with Nebuka—flies are specially grown and let loose in a cage that covers the emasculated seed parent and also contains a cut flower stalk of the pollen parent.

The onion has been used in interesting studies to develop methods of identifying specific chromosomes under the microscope, and there has been some genetic analysis of the inheritance of color and of certain abnormalities in chlorophyll development.

Peas and Beans

Peas apparently originated in Ethiopia, and according to one authority they are the only vegetable that can with certainty be traced back to the Stone Age. They are also the first crop with which controlled breeding was done to produce new varieties (by Thomas Andrew Knight, 1787), as well as the plant used by Mendel in determining the laws of inheritance that founded modern genetics.

They reached their greatest perfection in England, and many American varieties trace directly to the splendid products of the famous English breeders, beginning with Knight, who introduced the first sweet wrinkled pea. The most highly evolved variety so far is probably Laxton Progress, which blooms at the eighth or ninth node and is therefore a few days earlier than its nearest competitor, Hundredfold—a characteristic that, to pea farmers, was worth years of breeding effort.

American breeders received their greatest stimulus from the canning industry after 1900. Slight differences in such characteristics as pod size, pod curvature, tightness of peas in pod, number of peas in prime condition at one time, node of first bloom, and straightness of stem have been important breeding objectives to achieve the closest possible adaptation to machine handling and other needs of the industry. In garden peas, the chief American contribution has been a great reduction in the incidence of the defect known as "rabbit ear." Today, preservation by freezing presents new objectives; and with all types of peas, American workers are now concerned with breeding for resistance to fusarium wilt and other diseases, as well as to insects and adverse weather conditions. Active breeding work is being carried on by several State experiment stations, notably Wisconsin, by the United States Department of Agriculture, and by some of the larger seed companies.

Elimination of strings was the chief objective of the early commercial breeders of snap beans, and the most successful among them was Calvin N. Keeney, of New York, who produced many varieties still popular, including Burpee Stringless Green Pod, Giant Stringless Green Pod, Stringless Green Refugee, and Brittle Wax. Later, the ravages of disease made it imperative to give major attention to breeding for resistance. New York State has led in breeding beans resistant to anthracnose. The Michigan, Idaho, and Wisconsin stations, the United States Department of Agriculture, and the Department in cooperation with the Wisconsin station, have produced varieties resistant to mosaic, and some of these are tolerant to bacterial blight. Strains resistant to bean rust have been bred by the Department and by the Virginia station. Thus the major bean diseases have been overcome to some extent, and the work is being actively carried on to make greater gains.

Little controlled breeding work was done with lima beans until a project was recently started in the Department. All the present varieties resulted from selection. Of the two most extensively grown today—Henderson Bush and Fordhook (also a bush lima)—the former was found on a Virginia roadside by a Negro laborer in 1885 and sold originally to a seedsman in Richmond, and the latter was

discovered growing in a field of pole limas in California in 1903. A hardy, high-yielding strain recently selected by the California station came from stock grown by the Hopi Indians.

Considerable genetic research has been done with peas, although this plant proved to be far more complex genetically than Mendel's early work would have indicated. To date, 68 genes have been listed. Research in bean genetics has also been extensive, and the inheritance of disease resistance has received, and is still receiving, a good deal of attention. Very little genetic research has been done with the lima bean.

Cabbage and Its Leafy Relatives

At least 4,000 years ago men were eating the leafy wild cabbage found on the coast of Europe and northern Africa; and this plant is supposed to be the original ancestor of such varied forms as the cultivated cabbage, cauliflower, broccoli, green-sprouting broccoli, Brussels sprouts, kale, collards, and kohlrabi. For our modern varieties of these vegetables we are largely indebted to farmers and to the assiduous work of commercial seedsmen, in both Europe and the United States, beginning in the late 1700's.

The most important single achievement in modern cabbage breeding in the United States has been the development of varieties resistant to yellows (fusarium wilt)-- an achievement that has saved growers from ruin in many sections and paid an enormous return on the cost. The problem was first attacked in 1910 in Wisconsin by L. R. Jones; and later J. C. Walker, of the Department of Agriculture, and his associates devoted many years to it. As a result of these intensive attacks, the wilt risk is now eliminated and there are yellows-resistant cabbage varieties of all the major types.

New varieties of cabbage that show improvements in other ways have been developed in Pennsylvania, Louisiana, and New York; and at several other State stations, as well as in the Department, breeding programs are in progress that promise worth-while results. The chief objectives today relate to diseases other than fusarium wilt, improved ability to hold up well in storage, better adaptation to particular localities, and a closer approach to consumer preferences, which favor a small or medium-sized hard head, mild or sweet in flavor, with crisp or succulent leaves.

Cauliflower and kohlrabi seed cannot be grown most successfully in this country, but broccoli seed can be, and new strains that mature at different times have been developed by private seedsmen in California. Green-sprouting broccoli has also been improved by breeding. New strains of Brussels sprouts have been privately produced in Oregon, and a new strain of kale has been released by the Virginia Truck Experiment Station. The Louisiana Station has introduced a new strain of collards.

One outcome of the breeding work with cabbage has been the development of interesting practical techniques for handling the plants and inducing the setting of seed under unusual conditions. Self-sterility is a problem with this plant, and as a result of intensive study much light has been thrown on the nature of self-sterility and self-incompatibility not only in cabbage but probably in other plants also.

Wide crosses between the cabbage and other species of the same genus have been fruitful in yielding cytological information, and there have been genetic studies of the cabbage concerned with the inheritance of characteristics of the leaf, the head, and the stem, as well as of plant height, bolting habit, season of maturity, and yellows resistance. Some work has been done on locating certain genes in definite chromosomes.

Root Vegetables

The turnip, rutabaga, radish, beet, carrot, parsnip, salsify, and taro are biennial plants, which means that they store a rich supply of food (mostly starches and sugars) in their roots during the first season to support growth during the second season, when they produce seed. Early in his history man learned to take this food supply for his own nourishment, just as he learned to steal the store of honey from the bee.

Over a long period of time improvements were made and definite types were set in these root crops by crude selection. Even in our own times, practically no other kind of breeding work has been done with them. But though the results of mass selection have in some cases been excellent—as with the carrot—the method no longer meets modern needs. In particular, the attacks of diseases and insects make it imperative to develop resistant types by the newer methods of inbreeding, crossing, and the introduction of valuable germ plasm from wild forms of these species.

There is very little work of this kind to report. On the other hand, there has been some interesting genetic research with these plants, and the unusual difficulties that some of them offer in breeding technique have been ingeniously overcome. The road has been cleared to some extent for going ahead with practical breeding programs based on definite objectives.

In order to "purify" the genetic make-up of a plant as a basis for combining desirable characteristics by crossing, it is necessary first to inbreed the plant. This is difficult in the case of some of the root vegetables. Turnips, rutabagas, radishes, and probably beets contain genes that make them sterile to their own pollen or pollen of certain other plants of the same variety. The mode of action of these genes has now been worked out. They are recessives and must be present both in the pollen and in the ovule to produce self-sterility. Their characteristics can be overcome to a considerable degree by applying pollen to a bud before it opens; or they can be replaced by "normal" genes through appropriate crosses; or naturally self-fertile lines can be discovered by enough searching and the others discarded.

In the case of the beet, the extreme dustlike fineness of the pollen, which can float in through tiny crevices, makes accurately controlled pollination difficult. This has been overcome by suitable techniques. The carrot was long thought to be self-sterile. Now it is known that the ovary merely develops before the pollen of the same flower is mature. Self-fertilization can readily be accomplished by using pollen from an older flower on the same plant. The flower parts are so minute that the usual methods of controlled pollination cannot be used, but this has been overcome by making flies do the work, inside special cages.

Along with such technical developments, research has uncovered facts about the inheritance of characteristics in these plants, some of which are of importance agriculturally—for example, bark and flesh color of turnip and rutabaga; color, corkiness, early and late flowering in the radish; color of root and top, and root shape in the beet; root color in the carrot. Investigation of chromosome behavior has also been fruitful. Certain wide crosses have been made, as between radish and cabbage, radish and Chinese cabbage, turnip and rutabaga, that may develop worth-while breeding possibilities.

Salad Plants

Since the public became vitamin-conscious, the salad crops—lettuce, celery, endive, chicory, cress, and parsley—have increased in importance. Very little scientific breeding work has been done with any of these plants except lettuce and celery, the major salad crops. The production of both is confined to rather specialized areas. Lettuce, one of the oldest vegetables grown, came originally from India or central Asia and was introduced into the United States early in the colonial period. Celery, native to the Mediterranean region, was long considered to be poisonous and has been eaten only in modern times.

Lettuce breeders have several solid achievements to their credit. Most notable of these is the development of the Imperial strains by I. C. Jagger, of the Department of Agriculture. This work was started in 1922 to meet the combined threat of brown blight and powdery mildew, which were on the point of wiping out growers in some of the largest western producing sections. The resistant Imperial strains, developed by hybridization, saved the industry in these areas.

Since transportation developments made possible the shipment of western lettuce to the East, eastern consumers have preferred the crisp western type. The present varieties of this type cannot be grown well in the eastern climate. A start was made in 1928 toward developing crisp-head types for eastern growers, and the first of these, Columbia No. 1 and No. 2, were released by the Department in 1936. A wholly new type of lettuce, Cosberg (a cross between Cos or romaine and Iceberg) was also introduced in 1936. This is comparatively free from tipburn, which is very troublesome in the East. The Department is now cooperating with several eastern State stations for the development of other crisp types adapted to local conditions.

Tipburn and mildew are both serious in greenhouse forcing. The Ohio station has developed a tipburn-resistant strain of Grand Rapids, and the Massachusetts Station a butter-head type, Belmay, resistant to mildew.

Celery growers need earlier maturing plants and plants resistant to yellows, premature seedstalk development (bolting), and pithiness. Breeders have been attacking these problems. Michigan released its Michigan Golden Yellows Resistant celery in 1933 and its Curly Leaf Easy-Blanching (also yellows-resistant) in 1936. A new Non-Bolting Golden Plume has been introduced by a private seed concern in California. Pithiness has now been proved to be an inherited characteristic, which paves the way for breeding nonpithy strains.

Although lettuce flowers are difficult to handle in breeding operations, some genetic studies have been made on the mode of inheritance of various characteristics, including plant height, time of flowering, habit of growth, length, width, and area of leaves, and particularly color. Genetic studies in celery indicate that pithiness is due to a single dominant gene, and that bolting may also be a dominant characteristic controlled by several genes but greatly influenced by environment.

Sweet Corn and Popcorn

Some of the greatest advances in breeding technique in recent times have been made with field corn—in particular, the method of crossing certain inbred lines to produce a hybrid that has remarkable uniformity and productiveness. These advances have naturally been reflected in sweet-corn breeding also.

Two outstanding needs have dominated breeding work: (1) The canning industry requires stocks that are as uniform as possible in every way, besides having high yield. (2) The fact that sweet corn cannot be grown in the South, largely because of the ravages of the corn earworm and of bacterial wilt, makes it highly desirable to develop resistant varieties.

Breeders have met the first need so effectively with the newer types of hybrid corn that the canning industry itself has been revolutionized by the uniformity in texture and consistency of grains and the uniformity of ripening in the field. Whole-grain canned corn, frozen packs, and new machinery have been made possible by the work of breeders. About 80 percent of the yellow sweet corn grown for canning now consists of the newer hybrids, and about half of this is Golden Cross Bantam, a product of the Department in cooperation with the Indiana station. Other States that have led in recent breeding work have been Maine, Illinois, Connecticut, and Minnesota. Not the least of the advantages of Golden Cross Bantam corn is its resistance to bacterial wilt.

Promising work is in progress to meet the second major need—extension of the sweet corn region southward—by hybridizing sweet corn with the naturally earworm-resistant dent field corns of the South. The factors that make this dent corn resistant to the earworm have not yet been satisfactorily determined, but varieties developed from sweet-dent hybrids like Honey June and Surecropper Sugar have more resistance than any other sweet corn. Leaders in this work have been the stations in Texas, Florida, Georgia, and California. Truck and home gardeners in the South are keenly interested in these efforts.

The characteristic kernel composition of sweet corn, which distinguishes it from field corn, depends on a recessive form of the gene for starchiness. The presence of this recessive prevents the conversion of some of the sugar into starch. A good deal of work has been done on inheritance in sweet corn.

Popcorn pops because the horny endosperm in which the starch grains are embedded confines the steam generated by heat until it develops sufficient force to explode the kernel. Popcorns differ in popping expansion, and the differences can be easily measured. They also differ in tenderness and flavor of the popped kernels, productive-

ness, and resistance to diseases and insects. Fortunately high poppability and tenderness seem to go together, but unfortunately high poppability and productiveness do not, so that in breeding a compromise is necessary between these two characteristics.

Breeding work with popcorn has been relatively limited, but it has produced some promising results. Mass selection, based on actual popping tests or on a rough comparison of the amount of soft white starch in kernels (the more starch, the less popping expansion) is useful in bringing about a gradual improvement in popping expansion, at least up to a certain point. The improvement in a 6-year experiment conducted by the Department in cooperation with the Kansas station was about 36 percent, and the improved strain has been distributed as Supergold. Hybridization of inbred lines has been carried on by several stations. At the Minnesota station, 250 lines of a selection of Jap Hulless were developed by inbreeding, then culled to 7 lines by selection, and all possible crosses were made among the 7 lines. One cross was selected as superior; the hybrid, named Minhybrid 250, has had a 16-percent higher yield and a 29-percent higher popping expansion than the Jap Hulless used for comparison. A continuation of this project with new inbred lines is now in progress in Minnesota. At the Iowa station, a promising three-way hybrid is now under test, and a group of inbreds is in the developmental stage. In a cooperative project between the Department and the Kansas station, 81 hybrids have been produced recently, of which about one-fourth show some improvement in popping expansion, and almost 90 percent show a marked improvement in yield. The Michigan station is now carrying on an interesting experiment in producing synthetic varieties by combining a fairly large number of inbred lines.

Injury caused by diseases and insects is a distinct drawback in commercial popcorn. In the case of some diseases, selection for commercial characteristics tends also to bring about some selection for resistance. In the Southern States particularly, damage from the corn earworm and from storage insects is serious. The Texas station has a project under way in which an attempt is being made to introduce the insect resistance of their adapted field corn varieties into popcorn of good popping quality.

POTATOES

Native to cool regions in South America, potatoes were taken to Europe by early Spanish explorers and grown there for a hundred years before they were introduced into the New England colonies from Ireland (1719, Londonderry, N. H.).

For another hundred years, little improvement was made in varieties. Then there was a rush to produce better potatoes. A minister, Rev. C. E. Goodrich, of Utica, N. Y., laid the foundations for potato breeding. He thought the ravages of late blight were due to loss of vigor through long vegetative reproduction by tuber cuttings, and he proposed to restore vigor by growing plants from seed. Some 170 varieties can be traced back to a single one of his seedlings, Garnet Chili. C. E. Pringle, of Charlotte, Vt., was the first to make systematic attempts to obtain seed by controlled hybridization.

In the United States today, potato breeding is extensive and well organized under a national potato-breeding program. Under this program, the Department coordinates the work in 13 States that are carrying on active breeding projects, with 21 States cooperating in testing worth-while material developed in these projects. Regional problems are considered, and States in which seed cannot be grown obtain it from States in which it can be grown. The various Department field stations and State agricultural experiment stations stress different aspects of the general problem, but altogether practically every aspect of potato breeding receives attention, including disease resistance, yield, adaption to locality, earliness, tuber shape, smoothness (depth of eye), cooking quality, breeding methods, genetic analysis, and study of chromosomes.

The breeding methods include the full range of those used in modern plant breeding—the introduction of new varieties or species, selection of colonal lines, crosses between varieties, brother-sister crosses (sibmating), backcrosses to parents, selfing and the recombination of selfed lines (as in the breeding of hybrid corn), outcrossing to unrelated strains, the synthetic building of strains by a combination of various methods, and wide crosses between different species (as between a cultivated and a wild form).

The outstanding problem is resistance to diseases, including a whole group of virus diseases, late blight, common scab, fusarium wilt, rhizoctonia, early blight, blackleg. These diseases add enormously to growers' costs. Late blight, the most important, has caused losses of 9,000,000 bushels of potatoes a year for the last 10 years; in 1928, the loss was 28,000,000 bushels. The severest possible tests for resistance are given, and so far very promising progress has been made in the development of many varieties resistant to late blight, a large number resistant to scab, a large number resistant to mild mosaic, and one variety and several of its progenies immune from latent mosaic. The search for disease resistance will be continued until every possibility has been exhausted.

From a practical standpoint, six new varieties have been named and distributed in the last 5 years (Katahdin, Chippewa, Golden, and Houma by the Department; Warba and Red Warba by the University of Minnesota). Another, not yet named, is being tested by farmers. Katahdin and Chippewa are now firmly established as commercial varieties.

With a wealth of available breeding material, breeding methods well tested, considerable genetic and cytological information, and a planned cooperative program, potato breeders are in a position to expect further progress with confidence.

Strawberries

The strawberry is not of ancient lineage as a cultivated fruit, though the Indians of Chile were growing remarkably fine selections of the wild beach strawberry before the time of Columbus. Five plants of this type reached France in 1714, and these were crossed with the wild meadow strawberry of eastern North America, which had previously been taken to Europe. The result was a vigorous hybrid, the modern cultivated strawberry—a European creation out of Ameri-

can parentage, so welcome and adaptable that it is now grown from Alaska to New Zealand.

Since the strawberry is relatively so new, most of our varieties are products of breeding, though a few have been found as chance seedlings in the wild. These are natural hybrids of cultivated and wild berries, for many of the wild sorts now contain chromosomes obtained from the pollen of their cultivated neighbors. Extensive commercial production did not begin until after the Civil War, when the first firm-fruited variety, Wilson, made strawberry growing in the South possible. Today, 20 varieties created in the last 45 years (Gandy, the oldest, in 1885) account for over 99 percent of the total acreage, and 6 of these (Klondike, Howard 17, Aroma, Blakemore, Missionary, and Marshall) for 78 percent. Most of the 20 varieties were produced by private breeders, and several famous private breeders of outstanding varieties are still living and carrying on their work.

Systematic strawberry breeding is now being carried on by the Department and by the agricultural experiment stations in 26 States, as well as in Alaska and Hawaii. Hundreds of thousands of seedlings are constantly being grown, of which perhaps two in a hundred are selected as worthy of a first fruiting test, and a very small percentage pass the final rigid test and are named and introduced. At many of these stations the work is new and has not yet had time to produce results. The Department has released 7 varieties, Minnesota 16, New Jersey 1, New York 21, North Dakota 1, Oregon 1, South Dakota 2, Tennessee 1, and Alaska 1. Strawberry growers readily adopt improved varieties, and such new introductions will account for an increasing acreage in the future. Breeding work is also actively carried on in Canada, England, Norway, Sweden, Germany, Switzerland, Czechoslovakia, the Union of Soviet Socialist Republics, Japan, and Australia.

The usual method of breeders is to cross varieties and species and backcross to the parents. The newer method of inbreeding and combining inbred lines has been used very little, partly because the strawberry plant loses vigor so rapidly with inbreeding. This method will very likely be necessary, however, to eliminate recessive genes that probably account for susceptibility to certain diseases as well as for other weaknesses. There is considerable confidence today that the excellent characteristics of many varieties and of the three wild 56-chromosome species (meadow strawberry, beach strawberry, Rocky Mountain strawberry) can be combined in a few outstanding types suitable for the wide range of strawberry-growing regions. Broadly, the objectives today are greater resistance to several diseases, and possibly to insects and nematodes; greater resistance to high temperatures, low temperatures, and drought; better adaptation to long and short days; better dessert quality under adverse weather conditions; increased firmness and toughness of skin; and better adaptation to certain specific uses such as canning, preserving, freezing, and flavoring.

Fundamental research with the strawberry has been concerned with the inheritance of a few contrasting characters and with chromosome behavior, largely in crosses between species with different chromosome numbers.

Blackberry and Raspberry

By clearing the forests, Americans set up a vast natural blackberry breeding project, for in the clearings the sparse growth of blackberries became dense, and since all blackberries need cross-pollination, a multitude of natural hybrids arose. For the last 75 years or so we have been making selections from this pool of mixed germ plasm, which has been the source of almost all our commercial varieties, including Lawton, Eldorado, Snyder, and the dewberry or trailing blackberry Lucretia. However, in the West the Logan (Loganberry) came from a cultivated variety, the Young dewberry (Youngberry) is an artificially produced hybrid, and the Evergreen (Black Diamond) and the Himalaya are of European origin. Whether the Logan is a blackberry-raspberry hybrid is still in dispute.

Comparatively little systematic breeding has been done with blackberries by public agencies, but the Department and several of the State stations are doing some work. There is much interest in developing thornless varieties. This has been accomplished several times by the use of mutations, but unfortunately only the outer layers of the plant tissue carry the characteristic of thornlessness, and new plants developing from the inner layers—as they do in the case of root cuttings—are all thorny. Also, thornless plants generally tend to be sterile. Other major practical objectives in breeding are superior hardiness, productiveness, vigor, flavor, firmness, and size; smaller seeds; and resistance to diseases, nematodes, and drought. Many crosses have been made by the Department and by the New York, Rhode Island, and Texas stations, and a few improved varieties have been introduced as a result. Workers at the Texas station, and in England, have been especially interested in experimenting with blackberry-raspberry crosses, but none of these has as yet produced a worth-while commercial variety.

Both European cultivated red raspberries and selections from native wild varieties were probably grown in the United States before 1800, but the red raspberry did not become commercially important until after 1865, when an industry was founded on the famous Cuthbert variety, discovered as a chance seedling in New York. The best cultivated red raspberries were developed by definite breeding work, mostly by the State stations, far more than has been the case with blackberries, and since this work began a considerable number of superior varieties have been introduced, including such important ones as Latham, Chief, Ohta, King, and Viking.

Breeding work is being actively carried on by the Department and the experiment stations in New York, South Dakota, Illinois, Washington, Minnesota, Tennessee, and North Carolina, and many thousands of seedlings that have resulted from crossing and selection are being tested. This includes work with the black and purple raspberries, crosses between red and black and between American varieties and Asiatic species, and the development of fall fruiting or everbearing forms and of varieties adapted to special purposes. Among other results are the production of berries bigger than would have been thought possible 10 years ago, and considerable success with varieties able to resist or escape major diseases.

But there are still great possibilities for improving the red raspberry, notably by bringing together in a single combination some of the superior characteristics now found separately in cultivated American and European varieties. Moreover, a large number of wild varieties exist in Asia and elsewhere, with extremely varied characteristics of plant and fruit, that the breeder has hardly yet begun to use in his programs. New possibilities will undoubtedly develop as these are more systematically explored.

Currants and Gooseberries

White-pine blister rust is not passed from pine to pine; it goes from pine to currant or gooseberry and then back to pine. This is unfortunate for currants and gooseberries; they have had to be wiped out in a good many places to save the pines. Extension of the now greatly reduced acreage will depend largely on the development of resistant varieties.

There are two kinds of currants, red and black. Of the red currants, five species, native to Europe and Asia, are considered especially important for breeders, and most of the leading American varieties (Fay, Wilder, Red Cross, Diploma, and Perfection) came from two of them. These American varieties were developed between 1877 and 1887 out of material that had been coming from Europe almost since the first settlement of New England. The European black currant is useless for this country because of its high susceptibility to blister rust, but the American black currant—which also has golden or white forms—is more resistant. Four improved American black varieties (Tonah, Atto, Mato, Wanka) were introduced by the South Dakota Station in 1925.

Very little systematic breeding work has been done with currants by either State or Federal workers. The South Dakota station has worked with black varieties; a number of crosses have been made and are being studied in New York; Minnesota has recently introduced a red selection, Red Lake; and Federal workers have made some crosses and selections but have introduced no varieties as yet. The most promising rust-resistant variety is Viking, an introduction from Norway. It seems in fact to be immune and is now being extensively tested by the Department cooperating with State stations. There are promising possibilities in breeding work with currants, especially the hardy, drought-resistant, vigorous American black varieties.

Greater promise, however, lies in the work with gooseberries. The greatest development of this fruit has been among the English, who became connoisseurs of gooseberries, held gooseberry shows, and offered prizes that stimulated breeding work, especially for large size. In the United States, gooseberry growers were discouraged by mildew until after 1900, when fungicides were used to control the disease. The most important gooseberry in this country has been Downing, a mildew resistant variety introduced about 1855. Poorman (1896) is the largest American-European hybrid. About a dozen species native to the United States are promising for breeders. They have a wide climatic range and such valuable characteristics as resistance to mildew, leaf spot, and high summer temperatures. These characteristics need to be combined with the great size, fine flavor, and attrac-

tiveness of European varieties, and some of the hybrids developed show the possibilities.

Breeding work has been carried on by several State stations. The South Dakota station has made crosses between a native wild species and European varieties, and these have resulted in some dozen introductions. The North Dakota station has recently introduced three varieties from crosses and is studying the inheritance of important characteristics. The New York station at Geneva has introduced one variety, and the Minnesota station has introduced an improved variety. The Illinois station is working for greater production, larger size, higher flavor, fewer thorns, and resistance to leaf diseases. The Department is doing some selection and hybridization, and has recently introduced one gooseberry, Glenndale, adapted to the upper South.

The breeding of both currants and gooseberries has been actively carried on in Canada, and in England research work has proceeded far enough so that the use of X-rays to induce mutations is now being studied. Breeding work is also being done in Sweden and in the Union of Soviet Socialist Republics.

Unusual Bush Fruits

All cultivated plants came originally from the wild, but only the most outstanding or the most adaptable have been extensively grown by man. Others from which men gather food might be adapted to cultivation and improved by breeding, just as the wild blueberry has been adapted and improved in recent years. Among the plants useful for landscaping there are also a number that might yield new forms or be made more valuable in other ways, if breeders would give them systematic attention. For example, columnar deciduous trees other than the Lombardy poplar might be created by breeding and would be extremely useful.

A few ornamental plants whose fruit is promising as food have received some attention. The actinidias (Chinese or Japanese gooseberries) are climbing shrubs bearing fruit up to the size of an egg, with a texture like that of a fresh fig, edible fresh or as a jelly or a cooked sauce. A single vine may produce several bushels of fruit in some years, but the need is to develop types that will bear regularly. The American cranberrybush or highbush cranberry (a close relative of the elderberry) produces fruit that makes a highly colored jelly of strong flavor. Several State experiment stations have cooperated with A. E. Morgan and the Department in improving this fruit by breeding, and three varieties are now available commercially. The goumi, or *Eleagnus*, has a tart fruit that is good in sherbets and is of considerable importance in central Asia. The plant is hardy and drought-resistant and might well be improved by breeding. The fruit of the oriental or flowering-quinces (Japanese quince is a common form) is extremely useful for jellies and preserves in combination with other fruits because it is rich in pectin and contributes an agreeable acid flavor. By breeding, it should be possible to develop larger fruit, with more acid and pectin and better color, which would be of great value in the preserving industries. The Chinese bush cherry (Manchu or Nanking cherry) is now receiving attention for its fruit,

which has an attractive tang and an agreeable range of flavors and textures. This fruit too has commercial possibilities, and some breeding work has been done with it in Iowa, New York, and Massachusetts.

Blueberries

Only a short time before his death on January 9, 1937, Frederick V. Coville completed an article for this Yearbook describing his work in developing the cultivated blueberry from the wild blueberry. Dr. Coville served 49 years in the Department of Agriculture, and probably his work with blueberries will stand out as the most important achievement of a fruitful career. It founded a new and thriving industry.

The work began in New Hampshire in 1906 with a study of the fundamental facts in the life history of the wild blueberry. The first fact established was one not before known—that blueberries, rhododendrons, azaleas, the mountain-laurel, and many other plants require acid soils.

Next, methods of grafting, budding, division, layering, propagation of twig cuttings and root cuttings, and pollination were worked out.

Then plants with superior fruit were chosen for breeding experiments. The first one, a highbush blueberry found in a pasture in Greenfield, N. H., was named Brooks. To the excellence of this first berry, Dr. Coville attributed much of the success of many of its later descendants. Efforts were made to self-polinate the Brooks, without success, and after other attempts, this method was abandoned in favor of cross-pollination. Much later, it was found that in cross-pollination, chromosome numbers were all-important. Even distantly related plants with the same number of chromosomes would cross, but if they did not have the same chromosome numbers, the cross yielded no fruit.

The second wild blueberry chosen was Russell, also from New Hampshire. In 1911 this was crossed with Brooks, and some of the first-generation hybrids were crossed with each other. Among 3,000 second-generation progeny, there was much segregation for various characteristics.

Thereafter, Dr. Coville made an intensive search for superior wild berries, enlisting the cooperation of Elizabeth C. White, of New Lisbon, N. J. Up to the year 1936 about 68,000 pedigreed blueberry seedlings were fruited and carefully tested for superior characteristics of bush, size of fruit, ease of picking, size of scar when picked, size of calyx, keeping quality, firmness, tendency to crack, and flavor. Taste tests were especially exacting and, with the consumer in mind, Dr. Coville would release no variety, no matter how remarkable its size or how good its other commercial characteristics, unless its flavor met his standards.

The largest berry developed in this work had a diameter of more than 1 inch, but it was not released because of inferior flavor. A hybrid between this and the finest-flavored berry, Stanley, has so far reached a diameter of nearly 1 inch. It is not yet ready to release, but Dr. Coville named it Dixi. His article describes the characteristics and ancestry of all his improved varieties—Pioneer, Greenfield, Cabot, Katharine, Rancocas, Jersey, Concord, June, Scammell, Stanley, Redskin, Catawba, Wareham, Weymouth, and Dixi.

Apples

To evaluate a new apple variety takes 25 years from the time the cross is made, and another 5 to 15 years will elapse before it is in commercial production. Practically speaking, the apple breeder works for his descendants, not for his own generation. Therefore as yet few of our widely grown varieties are the result of systematic hybridizing, even though this work was under way in 1895. Most of them came from superor chance seedlings. Apples were brought over from Europe by the early colonists, the seeds were widely disseminated, and since apples do not come true from seed, the range of differences in tree and fruit was very great. In fact this process extended back into early times. Primitive man appreciated the wild apple, though it was a wry thing, and he early began selecting and cultivating it. Budding and grafting were practiced over 2,000 years ago.

Today we need fruit with quite definite superior characteristics, and the hope of obtaining it lies in the extensive breeding programs of the present and the future. What are the objectives? Increased winter hardiness, of first importance in northern regions; disease resistance (the major diseases are scab, blotch, bitter rot, fire blight, and apple cedar rust); resistance to spray injury; late blooming to escape spring frosts in some sections; a combination of rich-flavored fruit with desirable tree characters (disease resistance, etc.); a greater range of fruits with high color and quality combined with ability to keep well in storage; varieties adapted to the far South—at present there are none that are satisfactory.

There is sufficient variation among the many different kinds of apples to give assurance that many of these desirable characters can be brought together in new varieties.

Three methods are available to bring about these improvements: (1) Keeping a careful watch for bud mutations; this has been practiced rather intensively during the last decade, and some very superior strains have resulted. The method is still highly promising, though it is limited to a relatively narrow range of improvement among existing varieties. (2) Hybridization to produce really new varieties by combining different characteristics. In some cases it is possible to go rather far afield; hardy crab apples are being crossed with commercial varieties of apples, for example, to get extreme cold resistance. (3) Producing varieties with unusual chromosome numbers. It happens that about 25 percent of our commercial apple varieties are triploids—that is, they have three full sets of chromosomes in their body cells instead of the normal two sets. Always these triploids have unusually large fruit and a vigorous type of tree; that is why so many of them happen to have been selected as superior. But the occurrence of triploid apples is very rare in nature, and so far it has been impossible to create them by controlled breeding methods. This is a secret that the apple breeder is trying intensively to solve.

Breeding projects are under way at the experiment stations in several States, and tens of thousands of seedlings are under test. So far, the Iowa station has introduced 13 named varieties; Minnesota, 5; Missouri, 7; New York, 15; South Dakota, 17. Work is also in progress in Idaho, Illinois, Maine, Maryland, Massachusetts, Ohio,

and Virginia, and the Department is doing a limited amount of breeding. A major program has been carried on in Canada, and apple breeding is combined with the breeding of other fruits in several European countries.

PEARS

Europeans have the same fondness for pears that Americans have for apples, and a great many delicious varieties have been developed in Europe. A Belgian physician, Von Mons (1765–1842), had as many as 80,000 seedlings in his gardens and developed over 400 varieties. At least as early as 1794, however, pears in the United States met the nemesis that has dogged them ever since. This is fire blight, a bacterial disease that attacks roots, crown, trunk, limbs, blossoms, and fruit. It is ruinously virulent in most of the East; in the West, relatively cool dry summers make it less destructive; but even there, it is a source of great trouble and expense to growers, since the only known method of control is by careful surgery.

Thus the fire blight menace dominates pear breeding in the United States. The European pear, source of all the fine-fleshed, buttery, melting, aromatic varieties such as Bartlett, Anjou, Bosc, and Winter Nelis, is especially susceptible. The Chinese or sand pear, coarse, gritty, and inferior, is resistant. Around the middle of the last century, hybrids between the European and the Chinese pear began to appear—Le Conte and Kieffer, for example. Although these are inferior in quality, they are about the only pears that have enough blight resistance to be grown in most parts of the East. One pear apparently of straight European parentage, the Seckel, is also resistant.

The problem, then, is to develop a wider range of the superior European varieties with resistance to the disease, either by hybridization or by selection. The most important basic breeding material includes the European pear (generally susceptible but with occasional resistant forms), the snow pear of southern Europe (susceptible), the Chinese or sand pear (variable resistance), the Ussurian pear of China and Siberia (very resistant, and especially valuable because the quality is fair), the Callery pear of China (resistant), the birchleaf pear of China (variable resistance). There is enough range in the available material to meet all requirements, including superior winter hardiness, which is needed in some parts of the country; but it may be another hundred years before the problem of fire blight is really solved, considering the length of time it takes to test a single generation of tree fruits.

The Oregon Station has led in this work. There F. C. Reimer has tested the resistance of practically all known species and varieties of pears, and of many hybrids, using artificial inoculation as well as natural infection. One of the most valuable breeding stocks is a highly resistant Anjou seedling called Farmingdale, found accidentally on a farm in Illinois. Ten other very resistant Eurpoean pears have been found in 10,000 seedlings, and all transmit a high degree of resistance in crosses.

The Department has also carried on fairly extensive breeding work for blight resistance, and 5,000 seedlings, inoculated each year, are now being grown to fruiting. Work has also been done in California (for range of ripening season), Georgia (studies of resistance), Iowa

(winter hardiness), Maryland, Michigan, Minnesota, New York (primarily for high quality and long ripening season), and Tennessee. Some new varieties have been introduced as a result of this work.

A limited amount of work has been done on the cytology and genetics of pears, but inheritance studies are difficult because selfing is impracticable in most varieties.

Grapes

Obedient to official urging and command, the early colonists in the eastern United States planted grapes of the traditional fine European varieties. All of these ventures failed miserably; the European varieties could not stand the diseases, the insects, and the cold that faced them in this part of the new land. In California, however, they throve ever since they were introduced by Mission Fathers from Mexico in 1769, and after 1850 grape culture in that State grew with great rapidity. Meanwhile, tardily, easterners began to become aware of the value of their own native grapes, which grew abundantly in the wild. Three chance seedlings—the Cape (believed to be identical with Alexander), discovered in 1806; the Catawba, first propagated in 1819; the Concord, named and introduced in 1854—had sufficient merit and popularity to turn the attention of breeders to these native species. Thereafter several men did notable work in selecting native varieties and hybridizing them both among themselves and with European grapes. Outstanding among these early workers were E. S. Rogers (Agawam), A. J. Caywood, Charles Arnold of Canada, G. W. Campbell (Campbell Early), Louis Suelter (Beta), J. H. Ricketts (Downing), and T. V. Munson, who originated more hybrids than any other man in the country.

Thus American grape growing has had two distinct lines of development. On the Pacific coast (especially in California), where 90 percent of the commercial grape culture is centered, European varieties are grown for the production of table grapes, raisin and currant grapes, and wine grapes; throughout the rest of the country, native varieties, hybrids between these, and hybrids with European varieties are grown for table grapes, wine grapes, and unfermented-juice grapes (the foxy flavor of the Concord, which is a fox grape, is important for this last use). Even the European grapes in California, however, must be grafted on native American rootstocks, which alone are resistant to phylloxera, an American insect that, finding its way to Europe, compels European growers also to use American grapes as rootstocks.

Grape breeding is actively carried on by the Department and by the State agricultural experiment stations in California, Georgia, Maryland, Minnesota, Missouri, New York, South Dakota, Texas, and Virginia. Many thousands of seedlings from an immense number of crosses are being grown and tested, and improved varieties have been released by the Georgia, the New York (Geneva and Fredonia), and the South Dakota stations. The general objectives in this work are improved fruit quality, disease resistance, and local adaptability; but there are separate objectives for the three main types of grapes. Thus, for American native bunch grapes it is desirable to have larger clusters and berries; some of the rich vinous flavor of the European grape; more edible skin, more melting flesh, seeds more free from the

pulp, increased sugar content. For the native muscadine grapes of the South, it is desirable to have larger bunches, better adherence of berry to stem, more tender skin, better flavor, smaller seeds. For the European grapes, it is desirable to have among the table types, more seedless varieties and a larger assortment of black, red, and white grapes ripening from early to late; among the raisin types, several improvements to meet specific needs; among the wine types, improved flavors (perhaps a blend of several flavors for certain kinds of wine), juice of better color, vines resistant to phylloxera to eliminate the necessity for grafting.

Needless to say, grape-breeding work is also being actively carried on in foreign countries, notably France, Germany, Italy, Czechoslovakia, the Union of Soviet Socialist Republics, and Australia.

Genetic analysis is slow, and there is need for more information on the inheritance of characters of importance, especially resistance to diseases.

Stone Fruits (Peach, Plum, Cherry, Apricot)

Grown in China thousands of years ago, the peach early spread throughout Europe and was brought to North America by the colonists; but commercial growing did not begin here until the nineteenth century, when orchards propagated from cuttings were first established. Between 1850 and 1900, peach growing became highly specialized, and to meet the need for types suited to different regions many varieties were developed by seedling selection, including such present stand-bys as Hale Early (1850), Belle and Elberta (1870), Crosby (1876), Champion (1880), Carman (1889), Rochester (1900).

Today, systematic breeding by hybridization is conducted by the Department of Agriculture and by the agricultural experiment stations in California, Illinois, Iowa, Maryland, Massachusetts, Michigan, New York, New Jersey, Texas, and Virginia, as well as in Canada. Many of these have only started recently, but the Department has introduced 4 varieties (1935), New Jersey 18 (1925–34), California 1 (1933), Iowa 1 (1932), Michigan 1 (1932), and Canada 6 (1925–30). The extent of some of this work can be realized from the fact that the New Jersey Station maintains 276 varieties of peaches and nectarines (a smooth-skin peach) on its breeding grounds for study and hybridization.

Objectives, of course, are different at different stations, depending on regional requirements and on the use for which the crop is intended. In general, there is still a need for a variety of high quality adapted to cold climates, and one that will not delay coming into leaf in climates where the winters are warm. Better varieties than Elberta—the best commercial peach so far—have been produced, but they are not so widely adapted. Promising hybridization work is now in progress with the Crawford type, which has very high quality, and with the J. H. Hale. A good deal of interesting genetic work has been done with the peach, but there is need for more.

Of the many species of plums native to various parts of the world, four are especially important commercially in the United States—the European plums, brought over by the first colonists, large, attractive, green and golden yellow (Reine Claude) to red and dark purple (Italian prune); the damsons of the Old World, yellow (Mirabelle) to blue

(Shropshire), small, tart, used for preserves; the Japanese plums, introduced into this country in 1870, yellow overlaid with red (Kelsey, Burbank), excellent flavor; the native American plums, especially the *Prunus Americana* species (De Soto, Weaver), red to reddish orange, good quality but a thick, tough skin and clinging pit. These species are rich in varieties available as breeding material, and there are also many other interesting species.

Several private breeders have done notable work with plums, including H. A. Terry and C. G. Patten, of Iowa, and J. W. Kerr of Maryland, who were interested in the selection of native varieties; Luther Burbank, who selected and hybridized Japanese plums and other species; Millard W. Sharp and A. F. and August Etter, of California, who are now engaged in hybridizing.

Much systematic hybridizing, both among the plum species and between plums and other stone fruits (cherry, apricot) is being conducted by State stations in California, Iowa, Minnesota, New York, and South Dakota, and by Federal field stations in California and North Dakota. Where the work has been longest in progress, as in South Dakota, New York, and Minnesota, several varieties have been introduced; elsewhere, promising material is still under test. The growing of plums has been declining in the United States during the last 20 years, and there is a great need for the breeding of varieties of really high quality adapted to regions characterized by extremes of heat or cold.

There are two species of cultivated cherries, the sweet and the sour. Sweet cherries are subdivided into two groups—heart or gean cherries, soft, tender, either dark colored (Black Tartarian) or light (Coe); and bigarreaus, firm, crisp, either black (Bing) or light (Napoleon). There are three groups of sour cherries—the amarelles, light (Montmorency); the morellos, dark (English Morello); and the marascas, native to Jugoslavia, used for making maraschino cherries. Duke cherries (May Duke) are probably hybrids between sweet and sour species Other species useful in breeding include the Nanking cherry of Asia; the sand cherry, the western sand cherry, and the chokecherry of the United States; and the mahaleb cherry of Europe and the pin cherry of North America, used as rootstocks

Commercial production of sweet cherries is practically limited to the Pacific and intermountain States, and that of sour cherries to regions along the Great Lakes The trees are too tender for colder regions; they do not thrive in hot, dry regions; and in hot, humid regions cherry diseases are disastrous. Breeding work is very much concerned with overcoming these major handicaps and making this delicious fruit available over a much greater area, and also over a longer season.

There has been little work by private breeders, though the development of black bigarreau varieties (Republican, Lambert, Bing) by the Lewelling brothers founded the cherry industry in the Pacific States. Among State stations, New York (Geneva) has taken the lead, introducing two new varieties so far. South Dakota has introduced several varieties, and work is in progress at the Iowa and North Dakota stations, the Federal field station at Mandan, N. Dak., and in Canada, where one new variety has been introduced. In

addition, collections of breeding material are maintained in Ohio, Colorado, Utah, California, and Oregon. In the search for necessary characteristics, native American wild cherries are being extensively used in some of this breeding work.

Apricots (probably native to China) are grown commercially only in Pacific Coast States because the blossoming habit of the trees makes them particularly susceptible to spring frosts in the colder regions. The species grown commercially is the common apricot, but several other species and subspecies are useful for breeding, including the black apricot, the Japanese apricot, the Russian apricot, and the Manchurian apricot. The raw material used by breeders consists largely of older varieties from England (Blenheim, Moorpark), from France (Peach, Guillans Early), and from the Union of Soviet Socialist Republics (Alexander, Budd), and newer American strains (Newcastle, Alameda). The chief objectives of breeders are to combine the good characteristics of these varieties and eliminate the faults; and also to develop hardier types adapted to a wider territory. Apricots from northern Asia are particularly hardy, but there is need for still more material of this sort.

Among the wide crosses that have been made is that of the apricot with the plum, producing the so-called plumcot—though some cytologists do not consider this a true hybrid.

Systematic breeding with apricots is quite new. The Department began work at Palo Alto, Calif., in 1922, and about 60 promising hybrids are now being studied and tested. Work began in New York (Geneva) also in 1922, and so far one variety (Geneva) has been named. In 1924 the North Dakota and the South Dakota stations began breeding work; the latter station has been experimenting with material from Manchuria and Siberia. Breeding work in Davis, Calif., began in 1930. Apricot-breeding projects are also in progress in Australia and Morocco.

Citrus Fruits

Grown for thousands of years in the Orient, citrus fruits were established in Florida by 1579 and California by 1769 and were worth over 134 million dollars to growers in the United States in 1934. They are an outstanding source of vitamin C and an important source of vitamin B. Their unique sprightly flavors come from a combination of sugars (sweetness), acids (tartness), glucosides (bitterness), esters (aroma), peel oil (aroma). The chief types, including those used as rootstocks, are sweet orange, sour orange, King orange, tangerine orange, satsuma orange, shaddock, grapefruit, pummelo, citron, lemon, lime, Ichang (lemon), kalpi, calamondin, and kumquat.

Today, large production, decreasing returns, and increased competition place great stress on improvement by breeding. Breeding work was begun in Florida by the Department in 1892 and by the State stations in California in 1910, in Florida in 1924, in Alabama in 1933, and in Texas in 1934. It is being carried on in Hawaii, Mexico, Brazil, Argentina, Spain, Italy, Greece, Morocco, Palestine, Japan, China, India, Zanzibar, Australia, and New Zealand.

Improvement of citrus fruits in the United States prior to the use of modern breeding methods was by introduction of varieties from

abroad, the selection of chance seedlings, and probably selection of some bud mutations. The record of the earlier development of varieties is full of interesting vicissitudes. Among the outstanding successes is the story of the Washington Navel orange. Through the help of a missionary, William Saunders, who was then Superintendent of Gardens and Grounds in Washington, D. C., got 12 navel orange trees from Bahia, Brazil, in 1870. Mrs. Eliza Tibbetts, migrating to Riverside, Calif., in 1873, took two of them along. They proved to be almost as important in California history as the discovery of gold, since all of California's Washington Navel orange plantings came from these two original trees.

The objectives of breeders today include: Tree characters—compactness, vigor, productiveness, disease resistance, cold resistance, congeniality with rootstocks, and correct market maturity. Fruit characters—high dessert quality, seedlessness or near seedlessness, correct size and shape, good shipping and storage quality, attractive exterior, standard vitamin C content, firm pulp for canning, and attractive juice color. There are other special requirements for rootstocks. In the past the chief methods of improvement were by: (1) Selection of superior seedlings without controlled pollination. Citrus fruits have the peculiarity of producing several seedlings from one seed. Usually only one is the product of the union of male and female parental cells; the others are practically buds within the seed tissue and are produced nonsexually. This adds to the difficulty of breeding work. (2) Selection of superior bud mutations. This has been very important since the intensive studies made by A. D. Shamel, of the Department, and his coworkers. In the last 18 years, probably 10 million buds have been sold to California growers alone as a result of this work. (3) Hybridization, especially between different species of citrus. This method is being used chiefly to create new types with unique flavors and other characteristics.

The last two improvement methods are still actively employed.

Hybridization is being carried on by the Department and State stations, with promising results in several cases. Almost every kind of citrus fruit has been crossed with almost every other kind. Among the new types produced are the tangelo (mandarin orange × grapefruit); tangelo × grapefruit; tangerine × sweet orange; Perrine lemon (lemon × lime); citrange (trifoliate orange × sweet orange); citrangequat (citrange × kumquat); citrangedin (citrange × Calamondin); limequat (lime × kumquat); tangemon (mandarin × lemon); tangor (orange × mandarin); orangelo (grapefruit × orange); oramon (lemon × orange); lemelo (grapefruit × lemon); lemon × grapefruit; lemon × citron. The hybrids are so numerous and varied that naming them is becoming a problem in itself.

In connection with breeding work, several technical problems are being studied, especially polyembryony (the asexual production of embryos) and the inheritance of disease resistance.

Subtropical Fruits Other Than Citrus

While many of the subtropical fruits important in other regions, such as the loquat, jujube, cherimoya, granadilla, jaboticaba, and white sapota, are relatively unimportant in the dietary and agri-

culture of the continental United States, others, such as the pineapple, fig, olive, avocado, and date, are the basis of established industries; and still a third group, including the mango, papaya, lychee, and guava, give promise of taking rank with those already firmly established. Most of those in the first group are adapted to one section or another of the United States, or to Hawaii, the Philippines, Puerto Rico, and the Canal Zone. With practically all of these fruits, breeding work and genetic studies are only at their beginning in this country, though there are some extensive and valuable collections of germ plasm made by such farsighted plant explorers as David Fairchild and Wilson Popenoe and their coworkers. Though the areas of possible cultivation are limited, interest in several of the subtropical fruits is growing, and with it the need for superior forms achieved through breeding. The raw material is fascinating in range and variety, and breeders are sufficiently well acquainted with it to have worked out techniques and determined the desirable objectives in considerable detail.

Fig growing is now the basis of a sizeable industry in California and Texas. Smyrna fig culture in California did not get into its stride until the discovery, at the end of the last century, that a small wasp, which makes its home in the inedible caprifig, is necessary for the pollination of quite a different type, the Smyrna fig of commerce. Improvement of figs—as of most other subtropical fruits—since that time has been largely by introductions from abroad and the selection of superior strains. However, hybridization has been conducted in California since 1922, and of some 4,000 hybrid seedlings that have fruited, several have been found with desirable characteristics. In Texas, hybridizing was started in 1935.

Avocado breeding is in the fortunate position of having a rich collection of varieties brought in by Wilson Popenoe and some of the early pioneers, available for hybridizing to obtain combinations of resistance to low temperatures, high quality, long range in marketing season, and other superior characteristics. These varieties are being intensively studied and several worth-while selections have been made. Although hybridizing has only begun, some excellent hybrids have already been secured and the future looks promising.

Thousands of date offshoots have been brought into the United States by the Department of Agriculture and others, totalling over 140 varieties, and of these some 16 varieties are now important in Arizona and California and many varieties are under test in Texas. Date breeding is an extremely slow process. Methods of controlled pollination have now been worked out, but progress so far has been by mass selection.

Pineapple growing has been revived in Florida since 1933; it is extensive in Hawaii, and fairly extensive in Cuba and Puerto Rico. Hybridization has been begun by the Department; some work is being done in the Philippines; but most of the breeding work is in Hawaii, where promising results are being secured.

The papaya, a "tree melon", is counted an outstandingly fine fruit by those familiar with the best varieties. Florida seems best adapted to papaya culture in the United States, though the fruit is grown in California and Texas also. It is very important in the dietary in Hawaii, the Canal Zone, and the Philippines. The Department has

introduced many strains and related species, and a breeding project is now in progress. Breeding work is also being done in Hawaii, the Philippines, and the Union of South Africa.

The mango, one of the oldest of cultivated fruits, with a flavor somewhat like pineapple and apricot combined, is grown in Florida—where over 200 introductions have been made by the Department, including more than 50 varieties and a number of related species—as well as in the island possessions of the United States. No method of controlled pollination has been worked out, but selection of superior seedlings holds considerable promise, and it is now being practiced in breeding for disease resistance and other characteristics.

Miscellaneous subtropical fruits with which little breeding work has as yet been done in this country include the olive, persimmon, granadilla, guava, feijoa, jaboticaba, pomegranate, jujube, lychee, loquat, white sapote, and cherimoya. All have possibilities for improvement and some are exceptionally interesting.

Nuts

Until recent years there was practically no attempt to develop better nut trees by controlled breeding. Nature's products usually seemed quite good enough. There is not much breeding work under controlled conditions today, but it has been started, and though the work has many difficulties, it also has very great possibilities for those with the inclination, the time, and the facilities to carry it on.

Chestnut breeding became a pressing need because the American chestnut, a magnificent tree characteristic of large forest areas in the eastern United States, was practically killed out by chestnut blight, a disease from the Orient that first appeared on Long Island, N. Y., in 1904. Some hybridization of American and European chestnuts had been done before the blight appeared, but the hybrids were doomed because both parental species are highly susceptible. The Japanese chestnut tree is quite resistant, but the nuts lack flavor. Much more promising is the Chinese chestnut (first extensively introduced into the United States in 1907), which is highly resistant to blight and produces a nut as large as the European and often as fine in quality as the American. Present selection and hybridization work, therefore, is practically confined to the Chinese chestnut, with consideration being given to the Japanese. The Department and the Illinois station are engaged in this work, as are several private breeders. No variaties have been officially released by public institutions as yet. Chestnut blight will quite probably be overcome by breeding and it is not impossible that another major enemy, the chestnut weevil, will also be overcome.

Commercial filbert growing is confined to a region in the Pacific Northwest, particularly the Willamette Valley of Oregon and parts of western Washington naturally adapted to the superior filbert varieties of two European species (Barcelona, Du Chilly, Daviana, White Aveline are well known horticultural varieties of these). In the eastern United States these European filberts are handicapped by a fatal blight, which spreads to them from the American species, and by lack of winter hardiness. A few somewhat superior American varieties (Rush, Littlepage, Winkler) are available for growing in the East, but

the breeding problem here is one of developing hybrids with resistance to disease and cold. In the Pacific Northwest, the problem is to develop filberts commercially and culturally superior to those now grown. There is a good supply of breeding material, and work is being actively carried on by the Department (at Beltsville, Md., and Corvallis, Oreg.), the Minnesota station, and the New York station at Geneva, as well as by several private breeders.

The breeding of pecans, the most important nut of the hickory group, is somewhat confused by existing uncertainties as to the sizes of nuts wanted by the market. The shelled-nut market wants very small pecans, and there is doubt as to whether they can be grown profitably except in uncultivated forest groves. The one-time demand for very large pecans has steadily diminished, so that breeding for extra size no longer seems desirable. In addition, most of the best of the older varieties of pecans proved to have so many drawbacks that the nuts are no longer marketed by varieties (as are apples and pears), but the varieties are blended. Nevertheless, selection and hybridization proceeds with certain definite objectives—hardiness (for northern pecans), disease resistance, fruitfulness, size of nut (at present a compromise), shell thinness, shelling quality, kernel quality. The work of the Department is divided regionally; the Illinois Station is carrying on a selection project; several private breeders are active; and pecan breeding by selection is being conducted in New South Wales and in Mexico.

Hickories other than pecans have received very little attention from breeders—the market demand is too limited. Nature has accomplished considerable hybridization between the various species (pecan, shagbark, shellbark, bitternut), and trees of some hybrid forms are available commercially. Hickories superior in thinness of shell, cracking quality, and flavor would fill a real need. A limited amount of selection work is being done by the Department of Agriculture, the stations in Illinois, Ohio, and New York (Geneva), and private breeders.

Breeding the Persian walnut (called English walnut because it first came to this country from England) has largely been confined to selection, which has about reached its limit of practicability. The next step is hybridization to develop varieties resistant to blight and possessing greater fruitfulness, superior hardiness, better cracking quality, and superior flavor. Such work is being conducted by the Department, the Minnesota and New York (Geneva) stations, and at least one private breeder. Selective breeding is being done in Mexico.

Selective breeding with the eastern black walnut is being conducted by the Department, the Illinois, the Minnesota, the Ohio, and the New York stations, and many private breeders. Similar work with the Japanese walnut (much like the butternut) is being conducted by the Connecticut station and several private breeders. The Department is now starting a project to create a form of walnut unlike any now existing by crossing the Persian walnut with the butternut for hardiness and flavor, then with the eastern black walnut and the Japanese walnut for sturdiness and fruitfulness of tree.

Almond breeding is being systematically carried on by the Department in cooperation with the California station at Davis, with the

objective of combining in a few new and definitely superior varieties as many as possible of the superior characteristics of the existing varieties. If this is successfully done, American almonds should not only dominate the American market but have a place in foreign trade. Practically no breeding work has been done with the pistache nut (adapted to hot, dry regions), though it deserves attention. The tung tree, the nuts of which furnish a valuable oil that dries more rapidly and is more resistant to water than linseed oil, was introduced into this country from China by the Department of Agriculture in 1905. The Florida Station began hybridization work in 1929, and the Georgia Station began selective breeding in 1933.

Very little genetic analysis has been made with nut trees, but a good deal of valuable technical work has been done on pollination technique, pollen viability, receptivity of the stigma, fertilization, and incompatibility.

Flowers

The enormous number of our named varieties of flowers has resulted from generations of breeding effort on the part not only of commercial growers but of untold numbers of amateurs from every walk of life. There are 15,000 varieties of roses alone, 8,000 varieties of tulips, 7,000 varieties of dahlias, 7,000 varieties of narcissus. Many of these are romantic in origin and testify to the deep love of the breeder for his work.

Yet most of this work has been unscientific in nature, and too much of it still is. Flower breeders, both amateur and professional, have on the whole had only a slight acquaintance with the modern science of genetics, which has played so important a part in the breeding of the more important food crop plants. They proceed by trial-and-error methods and wait for the breaks, and the result is much waste of time and effort, and the persistence of practices that cannot bring the expected results. Modern genetics goes out and makes the breaks. The time has come when those interested in breeding flowers should go to some trouble to study the facts and theories of heredity developed since Mendel's paper was rediscovered in 1900, and to master the technical methods that have revolutionized other fields of plant breeding. Genetics has a vast amount to contribute to the improvement of flowers, though professional geneticists have paid relatively little attention to ornamental plants except as these have been used as laboratory material for the study of theory.

Flowers differ in their requirements for pollination, depending on the structure of the flower parts and on different degrees of self- and cross-sterility. Emasculation (removal of the anthers) is quite commonly necessary in cross-pollination, and the bagging technique must frequently be used to prevent contamination with unwanted pollen. The older method of improvement was by selecting superior plants from a large mixed mass; it is still widely used, but it is slow and very limited compared with later methods. Then came line breeding, or selection from the progeny of a single plant. Hybridization, the most important method in plant breeding today, will probably be used more and more with flowers; but what some flower breeders fail to realize is the necessity for continuing the breeding work after the first hybrid generation, to provide segregating groups with different com-

binations of parental characteristics; and also the necessity for keeping the right kind of records. Unusual plants produced by gene mutations or by variations in the number, structure, or behavior of chromosomes are sources of valuable material, and some of the newer methods of artificially bringing about these changes seem promising for the flower breeder. This emphasizes the need for an understanding of chromosomes, which has contributed definite practical results—notably, for example, in the case of double-flowered stocks—and will contribute much more.

Representative flowers considered are the amaryllis, China-aster, canna, carnation, chrysanthemum, dahlia, gladiolus, hemerocallis, iris, lily, nasturtium, rose, snapdragon, double-flowered stock, and sweet pea. Some of these have a rich historical background and several have been subjects for much patient selection and hybridization. In two cases—the China-aster and the snapdragon—breeding has been responsible for the development of forms resistant to destructive diseases. In all cases there are as yet untouched opportunities for improvement through better breeding methods, a closer study of inheritance and cytology, or the use of germ plasm not yet incorporated into our cultivated varieties.

Miscellaneous Forage and Cover Crop Legumes

Among the Cinderellas of the plant world are many humble legumes—relatives of our common peas, beans, alfalfa, and clover—that are valuable for soil building and conservation because they will thrive where better-known crops fail, and they enrich the soil with nitrogen. Some are known as weeds; some have been grown by farmers here and in other countries both for forage and for human food. Not much has been done to study the adaptability of these plants to special conditions or to explore the possibility of improving them by breeding; but as this country passes out of the large spending stage in agriculture, they will be given more attention. Their use is like having a savings account in the bank.

A few of these plants are already of considerable value. The cowpea is extensively grown, a large number of varieties are recognized, and some State stations as well as the Department have carried on breeding work with it. At least one outstanding variety, the Victor—resistant to wilt and nematodes—has been developed by controlled hybridization, and others have resulted from selection. The field pea, also widely used, has given good results with selection and is now the subject of breeding programs by the Department and by the Georgia, the Alabama, and the Tennessee stations. The velvetbean is a leading legume crop in the Southeast; several superior varieties have resulted from selection over a period of years, and a breeding program with this crop would probably be profitable. A large number of species of vetch are in general use, and the Oregon station, cooperating with the Department, has led in developing improved varieties. The lespedezas or bush clovers, invaluable in southern agriculture, have recently been receiving considerable attention. New varieties have been introduced from Japan and Manchuria, and the Department has been carrying on active selection work, but the possibilities are by no means exhausted as yet. The bur-clovers are grown to

some extent and have received some attention from breeders, but the species has rich possibilities not yet explored. Rattlebox (crotalaria) is a new forage plant in the United States, and the Department, cooperating with the North Carolina, South Carolina, Georgia, and Florida stations, has been selecting early varieties. Kudzu and the peanut are grown as forage crops, but no breeding work has been done with them from this standpoint.

Among the completely or almost completely neglected legumes, some of which undoubtedly have potential value in the United States, are the milk vetches for arid conditions; beggarweed or tick trefoil; bonavist, long grown in Africa and Asia; the chickpea; fenugreek, grown to some extent in California; the grass pea and guar, both used in India for animal and human food; kidneyvetch, the subject of breeding programs in Wales and Denmark; *Lotus*, commercially important in Europe and Australia; lupine, now being bred by German and Russian workers; the pigeonpea, a valuable legume in tropical countries; sainfoin, long grown in Europe; serradella, used in Europe on acid sandy soils; *Sesbania*, adapted to wet soils in the South; sulla, used in Europe and Australia.

Interesting technical studies with some of these plants, both in the United States and abroad, have helped to develop fundamental facts useful in breeding.

Miscellaneous Grasses

Man lives largely on grass. His grains are grasses. His meat and milk are transformed grass; in the United States, grazing lands furnish nearly half the sustenance of livestock. In addition, grasses are of great importance in reducing erosion and maintaining soil fertility; and this country spends over $100,000,000 a year on private lawns, and some $90,000,000 on turf for other purposes. Systematic efforts to improve grasses by breeding are therefore of major importance. In the United States these efforts with the miscellaneous grasses are relatively new; many State projects were begun not more than 5 years ago -though sporadic work has been going on for a long time—and it is too early to expect results. The work is older in Canada, the British Isles, New Zealand, Australia, Sweden, Germany, Denmark; and probably more has been accomplished at Aberystwyth, Wales, than anywhere else. But modern genetics proves that plants must be bred for specific environments. We shall have to solve our own grass-breeding problems.

The sources of breeding material are as wide as the world, for each region, from desert to swamp, from the Arctic to the Equator, from mountain to sea beach, has its peculiar grasses, adapted to persist and thrive there. The number of grasses developed under these varied conditions is extremely large and the range in characteristics correspondingly great. Long ago the migration of grasses to other regions began. South American cattle live on forage grasses that originated in tropical Africa, cattle in the Corn Belt on grasses from Europe. The United States today may be divided into six regions from the standpoint of climate, and the major types of grasses in these regions into nine broad groups—Kentucky bluegrass, Canada bluegrass, and timothy; the redtop and bentgrasses; orchard grass and

tall oatgrass; Bermuda, Johnson, and Dallis grasses; carpet, Napier, Bahia, and Para grasses; awnless bromegrass and crested wheatgrass; native short grasses and prairie grasses; slender and western wheatgrasses; Sudan, reed canary, and other grasses.

What are the needs and possibilities for improvement by breeding? Shy seed production handicaps the use of many valuable grasses. Diseases play havoc in certain regions and with certain types. Some excellent grasses are not aggressive enough in growth to maintain themselves in competition with other plants; others are too aggressive to make possible the maintenance of desirable legumes in mixture. Some are not vigorous enough in renewing growth after grazing or cutting. For some pasture and range uses increased longevity is needed, and this may be largely affected by drought resistance and winter hardiness. Greater ability to thrive in wet and in saline soils is very important in some places. Some good grasses would be more useful if they were more palatable to livestock and had higher nutritive value. In turf grasses, texture, ability to withstand hard usage, and uniformity are of major importance. On all of these eight counts there are sufficient variations within the best-adapted types to give promise that breeding by selection or hybridization would accomplish improvements. Already, selective breeding work in the United States has furnished improved new strains, either introduced or soon to be ready for introduction, of Washington and Metropolitan bent, velvet bent, highland reed canary grass, tall fescue, tall oatgrass, Bahia grass, tift Bermuda grass; and in Canada, of slender wheatgrass, crested wheatgrass, bromegrass, and orchard grass. Twenty-three additional improved strains in Canada are being increased for more extended trials and distribution.

The manipulations in grass pollination by controlled methods are often as fine as jeweler's work and must be performed under a magnifier or microscope. Ingenious techniques have been developed, and much study has been given to flowering habits, to the question of self sterility, and to chromosome behavior, especially in wide crosses. There has been little work as yet on the mode of inheritance of characteristics.

Timothy

Timothy, the most important of the agricultural grasses, was first cultivated in North America, though it is of European origin. It received its present name, presumably, from Timothy Hansen, who introduced it into Maryland from New England or New York about 1720. In 1929, one-third of the total acreage in hay in the United States was all or part timothy. It is also widely used in pastures, being one of the most palatable pasture grasses to livestock.

Varieties and strains of timothy differ rather widely in earliness or lateness of maturity, length and degree of fineness of stems, width of leaves, tendency for the leaves to remain green, resistance to the principal timothy disease (rust), and in other ways. These variations are the basis for breeding improved kinds. The objectives of breeding programs include rust resistance, increased productivity, early varieties for the South, late varieties for the North, varieties adapted for hay production when grown in mixtures with clover or alfalfa, and varieties especially suitable for use in pastures.

Timothy is normally cross-pollinated, so that most of it is quite hybrid in make-up. Methods of breeding include repeated selection among open-pollinated strains, and also some self-pollination and crossing of inbred lines.

Up to the end of the last century, timothy was timothy; there were no improved varieties, as there were of wheat, oats, and other grains. In 1889, Willet M. Hays pioneered in making selections of timothy plants at the University of Minnesota, for increased productivity and a longer harvesting season. In 1894, A. T. Hopkins, a well-known entomologist, began making selections and continued the work for several years. Hopkins had a notable faculty for arousing enthusiasm in others over the possibilities in timothy improvement.

After 1900, timothy breeding was started at Cornell University and is still being carried on there. An early and a late variety, both somewhat rust-resistant, have been produced, and a number of technical studies have been completed. Other stations that have had timothy breeding programs include those in Iowa, Minnesota, Pennsylvania, Kentucky, New Jersey, and Wisconsin. Some breeding work was conducted by the Department from 1899 to 1909, and thereafter it was carried on more intensively in cooperation with the Ohio Station. The outstanding variety developed from this work is the Huron— late, leafy, rust-resistant—released in 1933.

Abroad, several varieties with regional adaptation have been developed at Svalof, Sweden, and at the Welsh Plant Breeding Institute, Aberystwyth, Wales. Notable among Welsh developments were low-growing types that root at the nodes, especially suitable for pasture. These have been tried only to a very limited extent in the United States. Timothy-breeding work has also been carried on in other European countries.

Technical studies with timothy include biometrical analyses of yield trials, determinations of chromosome numbers, seed production under self-pollination, self-sterility, and effects of selfing on vigor, yield, disease resistance, and other characteristics.

Alfalfa

Alfalfa, which means "best fodder" in Arabic, is very old. One writer has suggested that it was the "grass" on which Nebuchadnezzar fed when he was driven into the fields. It was fed to sleek chariot horses in ancient Rome. The Spanish conquerors of Mexico and Peru took the Indians' gold but brought them alfalfa seed. Forty-niners, sailing to California around the Horn, picked up some Chilean alfalfa and took it with them. It soon spread to other Western States.

It did not winter well in the North. But in 1857 Wendelin Grimm, a German immigrant, brought alfalfa from his homeland into Minnesota. For 50 years he stubbornly and patiently saved seed from plants that survived the winter. In the end, he had the one hardy alfalfa. Subsequently, experiment station workers made Grimm alfalfa famous.

This was both a boon and a drawback. Grimm alfalfa was so satisfactory that there was little incentive to develop other improved varieties. Nevertheless, between 1903 and 1915 a number of State and Federal workers were busy breeding alfalfa, and they did some

138904 —37——11

interesting work introducing varieties that are now standard—though the limitations of the methods they used were not then fully understood. This work was stopped by the World War, with its emphasis on food crops rather than feed crops.

Some years later, stands of Grimm and other alfalfas began to die out prematurely and alarmingly, first in Iowa, Kansas, and Nebraska, then in other Midwestern States. By 1925, Federal workers traced the mysterious destruction to the organism now known as the insidious phytomonas—*Phytomonas insidiosa.* Today it costs farmers several million dollars a year in lost alfalfa crops and expense of reseeding. This catastrophe put pressure on breeders to see what they could do.

Plant explorers of the Department have scoured the earth for alfalfas, bringing back a thousand different strains. None proved to be very resistant to the disease except some from Russian Turkistan, northern India, western China, northeastern Iran. The chief problem in the present breeding program, then, is to combine the resistance of these strains with the good commercial qualities found in Grimm and other American alfalfas. Dovetailing with this is another problem of developing strains especially well adapted to various broad regions in the United States. Other desirable objectives include heavier seeding, better forage quality, suitability for grazing, insect resistance, drought resistance, and higher protein content.

For a concerted attack on these problems, State and Federal breeders have recently organized the Alfalfa Improvement Conference, to insure close cooperation between all the workers concerned.

Work has been done on breeding technique; correlations between various characteristics in alfalfa; hybrid vigor; inbreeding and its effects; the possibility of making species crosses; and segregating and purifying strains for disease resistance and cold resistance, with the object of recombining them. The general genetic behavior of alfalfa has been explored, but little has been done on the inheritance of specific characters. Recently a number of workers have been interested in the cytological study of the plant.

Soybeans

In the Orient soybeans have been grown since time immemorial, and it has been said that some oriental countries could not exist without them. The plant was introduced into the United States (Pennsylvania) as early as 1804. Since 1890 most of the State stations have experimented with it, but it aroused comparatively little enthusiasm until the last few years. In that time its rise has been dramatic. Acreage has increased 110 times in 28 years, seed production 13 times in 15 years. The United States is now second in seed production to Manchuria, though still far behind that "Land of Beans."

The reason for this phenomenon is to be found in the versatility of the soybean. Every part of the plant is useful, and a tabulated list of uses takes up a page of fine print. Forty-five oil mills in the United States are now crushing soybeans; 40 concerns are manufacturing soybean food products; 75 factories are turning out industrial products made from soybeans.

Altogether, the Department of Agriculture and State stations have brought in some 10,000 selections for testing and experiment. Thirty-two stations and the Department are engaged in breeding work. About 100 varieties have been introduced for commercial growing since 1894. Yet the breeding work is only at its beginning, for several reasons.

The soybean is very particular in its local requirements. This means that special varieties for each kind of use have to be developed for each separate region or locality. This has long been done in the Orient. The uses themselves demand quite distinct characteristics. Thus beans grown for oil should have a high oil content and a high iodine number, which is associated with good drying quality. The lecithin content of the oil is also important for some industrial uses. Beans for certain industrial uses should have a high protein content. Beans grown for food protein should be high in the three amino acids, cystine, tryptophane, and tyrosine. Those grown to be cooked as dried whole beans should be tender and of excellent flavor. Those grown for use as green shelled beans must be especially adapted to this purpose. And so on.

Progress has been made in developing varieties for local use that meet these needs. But there is much still to be done. The breeder, however, has a wealth of material, and the measurements and tests already made indicate the range of some of the characteristics among different varieties. Oil content, for example, ranges from 12 to 26 percent, iodine number from 118 to 141, protein content from 28 to 56, lecithin content of the oil from 1½ to 3 percent; the percentage of the amino acids mentioned varies over a wide range. The breeder can choose and combine, build up this, reduce that. Diseases are not yet a serious factor with soybeans in this country, but it is known that resistance to several diseases varies also, and when that complication enters he has some information on which to proceed.

The soybean is a self-fertilized plant, and artificial crossing is difficult and tedious. Hybridization, however, offers the best means of combining desirable characteristics and getting a wide variety of segregates from which to make selections. The inheritance of a good many characteristics of the flower, stem, leaf, and seed has been worked out, and a beginning at least has been made in mapping the location of a few genes on the chromosomes.

Clover

The ancient belief that clover brings luck has proved to be abundantly true for agriculture. First grown as a cultivated crop in the sixteenth century, its use became the foundation for good farming practice. It is at once food for the land and food for animals. Systematic improvement by breeding, a recent development, is being carried on in several countries.

Natural adaptation has been the prime factor in developing regional strains of red clover—the most important of the clovers in the United States—that differ in productivity, winter hardiness, and disease resistance. For several years, these regional strains have been closely studied by the Department in cooperation with the Kentucky, Ohio, and Iowa stations, partly to determine regional needs, partly to dis-

cover superior plants that may be used in breeding. Broadly, the chief objectives for the three red-clover regions of the humid eastern United States are: Southern—disease resistance, especially to anthracnose; central—disease resistance and winter hardiness; northern—ability to withstand a long period of winter dormancy. In addition, powdery mildew, the potato leafhopper, and the clover root borer are clover enemies in all regions.

So far, anthracnose-resistant strains have been developed by the Tennessee and Kentucky stations, and the Department of Agriculture has during recent years cooperated in improvement of the strains developed by the Tennessee station many years ago. Lines resistant to powdery mildew have been developed in cooperation with the station in Wisconsin. Other developments are in progress in cooperation with the Illinois Station; and the stations in Minnesota, Pennsylvania, Tennessee, Indiana, New Jersey, and Idaho have red clover breeding programs under way. Abroad, nearly all European countries, and Australia and New Zealand, are doing breeding work with red clover, and in several of these countries superior strains have been introduced. Selection from natural stocks has played a large part in improvement programs, but the isolation of self-fertile lines and controlled crossing are also used. The Welsh Plant Breeding station has carried on important basic studies.

There has been no breeding work with white clover in the United States, but work has been done in New Zealand, Denmark, Sweden, Finland, and Wales. Crimson, alsike, subterranean, berseem, and Persian clovers have not been bred in this country, though some of them have received attention abroad.

Sweetclover, which was classed as a weed a few years ago, has had a phenomenal rise in popularity and now holds an honorable place in the agriculture of the north-central region and the Great Plains States, as well as in several foreign countries. Several varieties, resulting from selection and introduction from abroad, have been introduced by the Department of Agriculture, by several State stations, and by individuals. Canada leads in systematic breeding, and work is also in progress in Wisconsin, Minnesota, Kansas, Washington, Texas, Nebraska, Illinois, West Virginia, and Idaho, as well as in the Union of Soviet Socialist Republics and in Germany. One of the chief objects in all breeding studies is the development of strains low in coumarin, since the presence of coumarin or of closely related substances appears to make spoiled sweetclover hay toxic to livestock and lowers the palatability of the green plant. So far, the results in this direction are promising.

Studies have been made of fertility and sterility relationships in clover that have cleared up misconceptions, and pollination techniques have been developed. There have been some cytological investigations and genetic analyses, especially in sweetclover.

Hops

Beer is made with hops, water, malted barley and other cereals. The hops supply lupulin (resins and essential oils) which gives the beer its characteristic flavor, and tannins which help to clear it. Thus hop growing is vital to the brewing industry, though unfortunately for

growers, a small quantity of hops makes a great deal of beer. In Europe hop growing goes back at least to 768 A. D. Kings who liked hopped beer sometimes compelled farmers to grow hops by law; those who preferred beer without hops forbade farmers to grow them. Kings of the latter type were apparently in the minority, and in Europe much effort was devoted to improving hop varieties.

The hop is a peculiar species. It is a perennial vine, grown on poles or trellises, and extremely sensitive to sun, wind, heat, rain, insects, and diseases. Male and female flowers are borne on separate plants, though it is not unknown for a plant to change its sex, sometimes more than once. The hop of commerce is something like a fir cone but more papery and fragile, and it is borne only on the female plant. Fertilization is not necessary for the development of the hop, but the cone bears seeds only when the flowers are fertilized.

Commercially hop vines are repoduced by cuttings, like sugarcane and some other plants. Since the seed is always a product of cross-fertilization, the plants are of hybrid origin genetically, and seeds from the same mother will produce many different types. It is chiefly from these diverse seedlings that hop breeders get their raw material for superior selections. Hop breeding presents some especially knotty problems and has some difficulties similar to those of animal breeding. Because the male plant bears no cones, it is uncertain just what it contributes to improvement, even when controlled pollination is practised so that the nature of the male parent is known.

Breeding work in the United States is relatively new. It was started by the Department of Agriculture in 1900, but later the World War discouraged and prohibition finished it. Now, however, it is being continued again in cooperation with the Oregon station. The chief objectives are increased yield; favorable periods of maturity; resistance to several diseases, especially downy mildew, the bane of growers in various sections; and quality, an elusive character depending on type, color, soundness, and lupulin content. Of these, only the amount and quality of lupulin can be accurately measured by laboratory methods. The importance of quality may be better understood from the fact that at present brewers in this country frequently mix some European hops with their American-grown hops and usually pay a high premium for hops from Germany and Bohemia.

Thus far the breeding program in the United States has been concerned largely with making a close study of the available raw material so that an accurate catalog of plant characteristics may be available. It has been necessary to work out techniques for some of the more difficult problems such as control of pollination, evaluation of breeding methods, controlled development of the downy mildew disease, measurement of resistance, and determination of quality. With these difficulties on the way to solution, a basis is being laid for future breeding work. Good results with seedling selection in Europe indicate the possibilities, though improved European varieties have failed to give comparably good results in this country. Growers on the Pacific coast are now very much interested in hop improvement by breeding, and the New York (Geneva) station has also recently initiated a varietal improvement project.

Forest Trees

In forestry, genetics is almost a new word, and breeding as it is practiced with other economic plants is a virgin field. Economic pressure in the wood-using industries and the urgent national need to build up forest areas, however, have turned attention to tree breeding as a vital part of an intelligent forest program. There is ample evidence that, like other plants, forest trees differ individually in the characteristics that are of value to man; and the possibility of breeding superior individuals and populating large areas with their descendants, as is done with wheat and other crops, is one we cannot escape exploring.

Obviously there are difficulties not involved with small, quick-maturing plants, in many of which pollination is fairly easily controlled, and it will take a good deal of study and ingenuity to overcome some of these difficulties. The methods and possibilities, however, are fundamentally the same as with other plants. They include a clear formulation of the type of tree desired for a given use; the selection of superior individuals by extensive testing and observation; establishing pure lines where possible; as much use of vegetative propagation, by cuttings, etc., as possible, to reproduce superior individuals absolutely true to type; the crossing of strains, varieties, species, and genera, both to creat new types and to obtain hybrid vigor; a thorough study of polyploids—that is, individuals with an increased number of chromosomes in the cells beyond the normal number—as sources of especially valuable stock. At present, polyploids are receiving special attention because these plants with extra chromosomes are so often characterized by unusual size and vigor, but the enlarged cell size in some types of polyploids, resulting in coarseness of structure, may prove to be a drawback for many commercial uses.

It need hardly be said that research in the cytology of forest trees, particularly in cytogenetics, and in the mode of inheritance of characteristics, should be carried on along with a practical program. Much work is also needed to determine standards and tests applicable in the forest and in the selection nursery.

In every one of these fields, a beginning at least has been made. Fairly extensive tests are being conducted to determine superior varieties and individuals for both regional forest requirements and use requirements, and these tests include disease resistance, weather resistance, rapidity of growth, and other important characteristics. Hybrids, superior in various ways to either parent, have been made, a notable example being the creation of fast-growing poplar hybrids for paper pulp. Experiments are being carried on in methods of controlled pollination and vegetative propagation. Efforts are being made to devise better progeny tests—not an easy matter under practical forest conditions—and ways to reduce the time involved in testing. Perhaps the least work is being done in fundamental research in genetics; but so far there are very few geneticists in forestry—practically none in comparison with other branches of agriculture.

To other plant breeders the amount of breeding work in forestry would seem small indeed, and doubtless quite elementary in nature. Nevertheless, the foundations necessary for a science of forest genetics

are being laid, in the United States and in other countries. Moreover, the forest-tree breeder, challenged as he is by difficulties, is in the stage where he is filled with enthusiasm for the possibilities not only of eliminating some of the most costly mistakes of past forestry practice, but of adding something genuinely valuable to nature's own magnificent achievements in creating trees useful to man.

Angora Goats

The goat performs two useful functions. It cleans up brush, thereby saving its owner a great deal of work; and through its digestive processes, it converts the brush into food and clothing for man, in the form of milk, meat, mohair, and skins.

The domestic goat is probably descended from the pasang or Greek ibex of the Near East. The long-haired Angora was originally developed by the Turks centuries ago. The first importations to Europe were apparently made in the sixteenth century, and to the United States as late as 1849. South Africa, Turkey, and the United States are the leading producers today. There are now over 3 million Angoras in this country, and the industry is concentrated chiefly in the Southwest, with Texas well in the lead. Of the 15 million pounds of mohair produced in the six leading States in 1935, Texas produced 13 million.

Improvement of the Angora goat has been entirely in the hands of private breeders. In the range herds, it has been carried on by the method of breeding high-grade does to registered bucks that conform to the standards of the breed association. Very little research work on breeding or genetics has been done by public institutions. The Texas station has been the leader in this field, and at its branch station near Sonora it is now carrying on three active projects on inheritance of type, inheritance of cryptorchidism or undescended testicles, and cytological and hybridization studies.

The best present representatives of the breed produce up to 75 percent more mohair than the average for the country. But there is a very great lack of uniformity even in good herds. If further progress is to be made, a research program will be needed to work out better methods than those now in use to determine an animal's inheritance, and a far better knowledge of the mode of inheritance of characters concerned in the production of good fleeces. Research usually pays well, but there are many difficulties and complications involved in such a program, and it can only be carried on with the active encouragement of the industry.

Meanwhile certain practical steps might be taken by the industry that would tend in the right direction. Among these would be a system of pedigree recording based on production of mohair, with certification of the records, as with dairy cattle and poultry; the selling of mohair on a quality rather than a weight basis, to stimulate improvement of the breed from this standpoint; and the adoption of different methods of awarding prizes at shows, on the basis of get of sires and outstanding families rather than individual appearance—a practice that would be in line with the use of the progeny test, which is overwhelmingly important in evaluating breeding stock, whether plant or animal.

Milk Goats

The milk goat is a handy pocket edition of the cow, and it will subsist where the keeping of cows is impracticable. In certain areas and under certain economic conditions, it can be an important factor in contributing to the family food supply. The milk is not significantly different from cows' milk in nutritive value, and goat meat is palatable and wholesome. The official maximum production record in the United States, made by a Saanen doe, is nearly 7 quarts a day for a period of 9 months and 10 days. Average production is very much under this, and there is great variability between individuals.

Efforts to improve the productivity of milk goats in the United States, therefore, are worth while not only from the standpoint of the present industry, with its breeding and dairy investment, but also as one method of economically raising the nutritional level of some sections of the population.

In this country, only two projects have been carried on by public agencies involving research and experiment in milk goat breeding—one conducted by the Department, one by the New Mexico station.

The Federal project was started in 1909. It has consisted largely in grading up common American does by crossing and top-crossing with registered Saanen and Toggenburg bucks. Progress has been slow partly because of the very small number of breeding does used. However, the average length of the lactation period has been increased 145 percent over that of the native does, and the average annual milk yield by 335 percent. Analysis shows that the period of maximum production is between 4 and 6 years of age. Index measurements of the sires used show marked differences in ability to transmit superior inheritance to daughters.

At the New Mexico station, native does have been graded up by the use of registered Toggenburg bucks, and studies have been made of the inheritance of horns and wattles, length of gestation, prolificacy, sex ratio, and the effects of inbreeding and outcrossing on milk production and birth weight of kids. Marked increases in production were obtained from the top-cross does, and several does in the herd have made creditable records under advanced registry. Line breeding was practiced with three outstanding bucks, the results indicating that it would be worth while to continue this as an experimental procedure. Fertility in the herd was high, 144 parturitions producing 286 kids.

Other researches with milk goats include nutritional experiments with the milk and studies on the physiology of milk secretion, including the effect of pituitary extract on lactation. There has also been a limited amount of genetic research on inheritance of horns, wattles, short ears, color, cryptorchidism, multiple births, and a peculiar nervous instability.

Improvement of herds has been mainly in the hands of private breeders and their three registry associations. Considerable progress has been made, but more might be done by the keeping of more complete records; the development of a more extensive record-of-performance program; the more extensive use of proved sires through a system of exchanges; the elimination of factional tendencies among

groups of breeders; and the working out of better procedures for the selection of breeding animals. There is a need also for further research and experiment on the uses of goat products, and for more study of the economics of production.

Dogs

Dogs supplement the brains of men. Their usefulness depends almost entirely on intelligence and temperament. No other animal serves so many purposes; they are hunters, guards, companions, guides, messengers, herders, detectives, haulers and carriers, scavengers, and even, in parts of the world, sources of fur and food. It is surprising, then, that so little has been done in the way of systematic research in the genetics of the dog, in spite of the fact that in other fields--physiology, psychology, medicine--work with dogs has helped to make possible some major scientific advances of great benefit to humanity.

Scattered studies have furnished information on the inheritance of coat colors, which apparently depend on many genes, often with multiple effects. Certain characteristics of form and structure have also been studied, including the inheritance of modified secretion of the endocrine glands, which has been under investigation by Stockard at the Cornell University Medical College. Some work has been done on the inheritance of aptitudes, notably at Fortunate Fields, in Switzerland, where German Shepherd dogs have been trained as guides for the blind and for army and police service. Here marked progress has been made in breeding superior animals by assuming that valuable characteristics were controlled by a few major genes.

In practical breeding, dog competitions of various kinds have had a marked influence, since persistent winners at field trials and dog shows have a favored position as breeding stock. On the whole, this has probably been a good influence in dog breeding, though from the standpoint of sound scientific practice undue weight is given to the appearance or performance of the individual animal. Awarding prizes and selecting breeders on the basis of a genuine progeny test would put dog breeding on a sounder genetic foundation.

In some cases these contests have been responsible for splitting a breed in two different directions, one strain being especially adapted to perform well in the field, the other being notable for show points. The field competitions greyhound racing, dog-sled racing, hunting and retrieving contests, sheep-herding contests, obedience trials—are of interest as indicating certain kinds of measurements that would have to be developed in a program of genetic research so that one dog might be accurately compared with another.

What are the possibilities in genetic research for the future? There is little doubt that it would help to accomplish improvements in dogs themselves, especially in the development of types for special purposes. Beyond this, however, is the fact that dogs are probably better suited than any other animal for investigations in the inheritance of psychological traits. These traits are important in many farm animals; nothing is known about their behavior in heredity. The Department of Agriculture has recently made a modest beginning in an investigation of this sort, using the Puli dog—a sheep dog of

Hungary—which is being crossed with various other breeds. From these experiments it is hoped that worth-while information may be developed regarding the inheritance of intelligence and certain aptitudes of practical value in dogs, the influence of temperament in such problems as effective feed utilization, and the possibilities for similar investigations with other farm animals.

TURKEYS

Before the nineties, this country produced turkeys at the rate of 1 a year for every 5 persons. In subsequent years the blackhead disease, scourge of turkey growers, reduced this to 1 for every 15 persons. Recently research taught us how more nearly to control blackhead, and the number of turkeys has now risen to 1 a year for every 6.5 persons. But less scientific attention has been paid to breeding problems than to those of feeding, management, and disease control.

Our modern domesticated turkeys are descended from the North American or common wild turkey, of which there are five subspecies. Wild turkeys were apparently domesticated by the American Indians, and some of them were taken to Spain as early as 1498. Several European domesticated varieties were developed from this ancestry, and some of these were brought back to the colonies to become the foundation stock of our six present American breeds—the Bronze, the Narragansett, the White Holland, the Bourbon Red, the Black, and the Slate. The differences between these breeds are largely in plumage color.

Several major objectives stand out as desirable in turkey breeding, though little in the way of coordinated or intensive work has been done toward achieving them. (1) There is an increasing demand for a smaller bird to meet the needs of the average family. Hitherto, breeding has tended toward increased size. There is still a demand for large birds for hotels, etc., but they now actually sell at a discount because of the greater demand for smaller sizes. This situation can be corrected by breeding (2) There is need for improved body type to provide a larger proportion of meat to bone, especially on legs and breast. (3) Birds should be bred to reach market maturity at an earlier age. (4) Higher egg production is desirable, especially in making possible an earlier and longer laying season, which now covers a maximum of about 6 months. (5) Higher fertility and hatchability of eggs are desirable to reduce production cost. (6) Attention should be given to breeding for lower mortality, whether from disease or other causes.

In achieving such ends, use might be made of a breeding system based on production records, pedigrees and, progeny tests, such as that now used by progressive breeders of chickens. There is need for more trap nesting and pedigree recording to serve as a basis for isolating superior families and breeding from them. State and Federal agencies might well lead the way by developing strains notable for viability, quick maturity, and good market quality.

The small amount of genetic research with turkeys at State stations has been concerned with tracing the inheritance of plumage colors. The Department has experimented in making crosses between tur-

keys and chickens. All the hybrids died as embryos, though one lived almost to the hatching state. At its range experiment station in Montana, the Department carried on a 5-year inbreeding project which indicated the possibility of establishing inbred lines not inferior to outbred turkeys in fertility, hatchability, production, and weight of eggs. A similar outbreeding project was successful in improving fertility, hatchability, and production of eggs, and maintaining egg weight.

Ducks

There are places along the South Shore of Long Island, N. Y., where for many miles the air is filled with the quacking of ducks, and the creeks and small coves are white with the birds. This is the center of the commercial duck industry. The flocks are all Pekins, which are sold as "green ducks" at the age of 9 to 13 weeks, after a period of rapid fattening. Elsewhere in the country there are a few commercial duck farms, and ducks are raised as a side line on farms in every State. The Pekin is everywhere the outstanding breed, though the Rouen, Aylesbury, Cayuga, and Muscovy are also represented among the meat breeds; the Indian Runner among the egg breeds; and the White Call, Grey Call, Black East India, Mandarin, and wood duck among the ornamental breeds.

In the United States little has been done in the way of scientific duck breeding. Yet the best commercial flocks are remarkably uniform in the size and quality of the market birds, and remarkably efficient in fattening under good management; in 12 weeks they increase their weight 50 times. This uniformity may be in part due to the small number of Pekins in the original importations, from which nearly all the ducks of this breed are descended. As compared with chickens, the degree of inbreeding would be comparatively high, which would tend to make for homogeneity.

Duck breeders still rely entirely on their ability and experience in selection, and have not resorted to trap nesting, progeny testing, and the keeping of individual pedigree and production records. Mass matings are used exclusively, and the breeding birds are kept for only one laying season, on the ground that young birds lay earlier and are more prolific. These conditions preclude the keeping of individual records or the making of individual tests. Experimental inbreeding or cross-breeding is negligible or lacking, though the Aylesbury is sometimes crossed with the Pekin in England, and the mule duck, a cross of the Muscovy and the common domestic duck, is occasionally seen in this country.

In England trap nesting is practiced with the egg-laying breeds, and in the 16 years since individual records have been kept there has been great progress in improving egg production. The highest individual production runs over 360 eggs in a year, and there are many records of over 300 eggs. In egg-laying contests the average production per pound of body weight is much greater than is the case with chickens.

Ducks offer a virgin field for poultry-breeding research, especially in the inheritance of meat characters, since they are chiefly used for meat in this country. The same general principles should apply here as apply in the case of chickens. Research of this nature, however, is

not likely to be undertaken except in response to definite needs felt and expressed by those concerned in the industry.

Fur Animals

Breeding and genetic research is important in two ways in the conservation and improvement of fur resources. First there is the problem of maintaining the wild fur resources of the United States. There was a time when this country was the world's chief source of furs. Fortunes were made in the fur trade. Partly because of the lavish exploitation of fur animals, we no longer supply more than a third of our own needs. Meanwhile our demand for furs has increased, and little is done to conserve the fur animals we have left. An intelligent conservation policy requires, among other things, much more knowledge than we now have of the breeding habits and gestation periods of the animals in the wild. Studies of the marten made by the Bureau of Biological Survey, for example, show that this animal has a gestation period of 9½ months. This means that under any ordinary system of closed and open seasons, it would rapidly become extinct; in order to save the martens, it is necessary to prohibit trapping for several consecutive years. Similar accurate information on wild fur animals other than foxes is practically nonexistent.

The second need for research is in connection with the production of fur animals on farms. This is a rapidly growing industry in which an increasing number of farmers engage as a part-time enterprise. It is relatively very young, but it has now passed the early speculative stage and is settling down to a healthy basis. In 1923 the total value of silver fox pelts was less than $820,000; in 1936 it was over $8,000,000.

Fox farming has reached the stage where it needs the same kind of help from science that has long been given to other livestock industries. There is little in the way of a well-thought-out or scientifically tested procedure in present breeding practices. At the same time, fur color, which is the primary factor from the market standpoint, lends itself particularly well to inheritance studies and genetic analysis. A research project begun in 1928 by the Bureau of Biological Survey indicates what may be done in this direction. That study was an attempt to find out how the major types—the red fox; the standard silver fox, a mutation that occurred in Canada; the Alaska silver fox, a mutation that occurred in Alaska; and the cross fox, a hybrid between red and silver—behave in inheritance. Two pairs of genes, *A*, *a*, *B*, *b*, apparently accounted for these variations in color; and in breeding experiments, supplemented extensively from records of matings made by fox farmers, this genetic hypothesis worked out with remarkable accuracy, so that it was possible to tell, by referring to a genetic chart, just what results any given combination would give in a large population.

The Bureau is now engaged in a project to determine the inheritance of degrees of silvering in the pelts, since this is the fundamental basis of market classes. Both studies, however, have been limited by the small amount of funds available for such projects. There is need for more extensive research on this and other aspects of fur animal breeding by public agencies, both Federal and State.

Bees

The individual bee has such a painful and distracting way of making its personal importance felt that probably few of its victims have ever realized that in the United States bees are also the nucleus of a 35–50-million-dollar beekeeping industry, or that they give us much of our food supply by fertilizing blossoms. Both facts underscore the importance of breeding better bees.

The bee breeder, however, has a peculiar and in some respects an exceedingly difficult task. For example, he is confronted by at least five factors not faced by the breeder of other farm animals. (1) Bees mate in midair, and until recently it was impossible to make controlled matings, except in an uncertain way through the use of isolated mating yards. (2) The drone is produced by virgin birth and therefore receives its inheritance entirely from its mother. (2) The drone dies immediately after mating, and the queen mates only once in her lifetime; therefore their use in line breeding has been impossible. (4) The worker bee, which does the work of gathering and storing honey, is not fully developed sexually and therefore cannot be bred for a direct study of its inheritance, although it does at times produce males by virgin birth. (5) Identification of individuals and even races of bees often depends on very small points, which must be measured by special methods.

As a groundwork for breeding, it has been necessary (1) to study sex physiology and functioning, and (2) to develop physical measurements that can be used for identification.

The greatest hurdle was passed when methods were developed within recent years for artificially inseminating queens. This is now done in three ways—by taking spermatozoa from the male and introducing them into the female with a tiny syringe; by bringing about a compulsory mating between a queen and a drone, both held under constraint; or by removing the sex organs of the drone and inserting them in the queen. The first two methods were developed in the United States, the last in the Union of Soviet Socialist Republics. All three now involve the use of a microscope and delicate instruments. A limited approximation to line breeding may even be made by removing spermatozoa from a fertilized queen and introducing them into a daughter of the drone from which they originally came.

It remains to develop a technique for controlled mating under more natural conditions.

Progress has also been made in cataloging traits that will be useful in identifying individuals, tracing the effects of inheritance, and measuring colony behavior.

Meanwhile, without waiting for the uncertain appearance of useful mutations or for an exhaustive study of inheritance, the bee breeder is in a position to go ahead toward the goal of producing a bee better adapted to the needs of agriculture. He has several traits available in the germ plasm of the common black, Caucasian, Carniolan, Italian, and Cyprian races that it should be possible to combine—long tongue to reach deeper sources of nectar, gentleness, the tendency to make white comb cappings, reluctance to swarm, resistance to European

foulbrood and to common hive enemies, industriousness, and uniformity of body markings.

Some interesting but inconclusive work has been done on the ctyology of the honeybee. Genetic research has been scanty, but the inheritance of some characteristics has been studied, dominance and recessiveness has been determined for a few factors, and a few linkages have been worked out. It is known that Mendel worked with honeybees in his effort to determine the fundamental laws of inheritance, but unfortunately his notes have been lost.

Fundamentals of Heredity

Reproduction by means of sex involves the union of two cells, a male and a female, each of which carries a set of chromosomes containing large numbers of genes that determine hereditary characteristics. For example, when two parents with contrasting characteristics have been bred pure, the first generation resulting from their union has all the chromosomes and therefore all the genes of both parents. If a plant of this generation is selfed (the closest possible inbreeding), the characteristics of the original parent will begin to assort or segregate into groups among the offsprings of the second generation. The chromosome mechanism is such that all possible combinations come together if the number of second-generation offspring is large enough.

Thus beginning with the second generation, most of the progeny are not like either original parent but have different combinations or groupings of characteristics from both of them. In this wealth of new combinations of genes derived from two selected individuals, the breeder finds the particular combination he is looking for—or something that approximates it.

The segregation of characteristics occurs in definite ratios, first discovered by Mendel. They can be worked out mathematically from the fact that all possible combinations occur in a large number of progeny, but Mendel worked them out by observation and thereby found the clue to this fundamental law of inheritance.

A knowledge of the segregation ratios gives the breeder the clearest possible insight into the actual behavior of characteristics in inheritance, and in addition these ratios are of practical value in a number of ways. There are a great many different ratios because the effects of dominant and recessive genes, and various gene interactions, bring about many modifications of the basic numbers. The typical examples can be readily understood by patiently following, step by step, what actually happens in inheritance.

Other concepts constantly used by the breeder include linkage (the location of certain genes in the same chromosome), crossing over (the exchange of segments between two paired chromosomes), sex linkage (location of genes in the sex chromosomes), and mutations. All of these help to explain what actually occurs in nature and to define what the breeder can expect and what he cannot expect to accomplish.

Animal breeding does not lend itself to the same kind of neat and definite analysis for several reasons: (1) Selfing is impossible, and the closest inbreeding does not approach that in plants. (2) More progeny are required for many genetic analyses than can usually be

obtained with animals. (3) Most valuable characteristics in animals are quantitative (amount of milk produced, etc.), and such characteristics usually depend on relatively large numbers of genes interacting in complex ways. Nevertheless, there is an abundance of proof that animal inheritance works just like plant inheritance, and the basic concepts of genetics have been of enormous value in clarifying and improving animal-breeding methods. Even though the animal breeder will probably never be able to make the fine-spun analyses possible for the plant breeder, the newer knowledge of genetics is already reflected in animal-breeding practices, and it will undoubtedly make for more certain and more rapid progress, and fewer costly errors, on the part of those who will take the trouble to understand it.

Vegetative Reproduction

When plants are reproduced by means of cuttings, buds, tubers, runners, rattoons, or other vegetative parts, the breeding situation is different than when reproduction is by means of seeds.

A seed results from the union of two cells, male and female. Even if these come from the same flower or the same plant, many of the male and female cells will contain different chromosomal material unless the plant has been bred pure so that all its male and female reproductive cells have identical chromosomes. The differing chromosomes will be divided up among the progeny in such a way as to produce different types of individuals.

In reproduction by means of vegetative parts, there is no union of sex cells, and each new plant has precisely the same chromosomes as the plant from which it came. Exact copies of the original parent can be reproduced for any number of generations. Winesap apple trees have been reproduced by budding or grafting for many generations, and theoretically every Winesap tree today is exactly like its original ancestor of 200 years ago. Thus by the use of vegetative reproduction, all the trouble of "purifying" a strain is eliminated. Even the most mixed hybrid reproduces true to type. When this method is feasible, then, it is often a valuable short cut, especially where it is difficult- as in the case of many forest trees—to obtain true-breeding material from seed.

But occasionally the new individual is not exactly like the parent. Rarely, there are mutations in one or more genes in a vegetative cell, or some unusual behavior of the chromosomes, that make a part of the plant different from the rest. Usually this occurs only in one case out of several thousand. When the new form is valuable—as has been the case with some of the bud mutations of tree fruits—it too can be multiplied by means of vegetative reproduction.

On the other hand, this very ease of exact reproduction has limitations. The true genetic make-up of the breeding material is neglected; there is no need to know it, as there is in inbreeding and cross-breeding. Yet it is through the diversity of forms brought about by combining different chromosomal material that the modern breeder gets valuable additions to our economic plants. If he desires to make planned improvements, he must resort to seed production even with those plants that normally are reproduced by vegetative means. This has been amply proved, for example, in the case of potatoes and straw-

berries. By combining chromosomes, the breeder deliberately creates what he desires. When he uses vegetative mutations, he merely waits for nature to produce something that will be useful to him, trusting to trained observation to find it.

Do plants reproduced by vegetative means for many generations tend to run out or be weakened for the battle of survival? This has long been a popular belief. It may be said flatly that there is no real evidence that running out occurs. Where plants seem to run out it has been found in every case that the deterioration has been due to a virus disease or some other definite cause.

New Studies in Chromosomes

By studying the architecture of the molecule, chemists have been able to achieve marvelous results in synthesizing nature's products in the laboratory. How far geneticists may be able to go in this direction is not yet known, but new advances seem to be foreshadowed in the researches now being made on nature's methods of juggling chromosomes. Intensive study of the jimsonweed has been fruitful of knowledge in this field that may prove to have significant applications to breeding work with plants of economic value.

The present-day Mendelian analysis of inheritance, with its dominant and recessive traits, assumes that chromosomes go in pairs in the body cells. It is now known that they do not by any means always go in pairs. Rarely, there is only one of each kind instead of a pair. More frequently there are three or four of each kind, or even more. In some genera of plants, this arithmetical multiplication of chromosomes may run in a regular series, different species being characterized by different numbers of chromosomes in the set, though all the species in the genus have the same number of sets. This regular increase gives rise to what are called balanced chromosomal types, since the balance between the sets is maintained in spite of the additions.

But there are also unbalanced chromosomal types in which only a single set has an extra chromosome or chromosomes added to it. The balance within the cell is then disturbed; there is an excess of the material contained in the extra chromosome. Sometimes a complete extra chromosome or two is added to a set. Sometimes two identical half-chromosomes are added, joined together like a worm with a head at each end and the tails missing. Sometimes the addition is half of one chromosome and the opposite half of a chromosome from a different pair, joined together like a head and a tail from different worms. And so on.

Detecting this kind of jugglery within the cell might be interesting but academic if it were not for the fact that chromosomes carry the determiners of hereditary characters. Careful observation in jimsonweed shows that each of these changes results in specific alterations in the characteristics of the plant, both qualitative and quantitative. Large numbers of such changes have been classified and correlated with the addition or subtraction of whole chromosomes or different parts of chromosomes. The differences between races of jimsonweed in different parts of the world have been found to be due to rearrangement of chromosome material. In this way new kinds of chromosomes

have been produced, which have been used in building up new kinds of jimsonweeds. Types can be arranged in a regular series, and what effects will be produced by deleting or adding certain chromosome material can be predicted in advance.

From a practical standpoint, the significance of this lies in a possible increase in the controlled synthesis of plants of desired types. It suggests a somewhat different operation than that based on the usual analysis of unit factors alone. Cytological examination shows that many of our most valuable plants are characterized by unusual chromosome numbers of one kind or another. Can we repeat these deliberately, or bring about new and different additions and subtractions of chromosome material that will have significant effects? The experimental production of extrachromosomal types in jimsonweed is promising. Not the least interesting part of it is the fact that by suitable laboratory treatment of living cells such changes in chromosome material can be made to occur far more frequently than they do in nature.

Chronology of Genetics

The modern science of genetics is a fusion of several sciences and practices that for a long time developed separately—animal breeding, plant breeding, cytology, or the science of the microscopic cell, and certain branches of mathematics. If today men not only dare to dream of emulating and surpassing nature by creating new, improved forms of life, but actually do it on an ever-increasing scale, it is because they have a rich store of facts and theories on which to base their work—facts and theories contributed by patient researchers in many countries over many generations.

Both animal and plant breeding of a practical nature, of course, are very old, but all of the early work was hit-or-miss and uncertain, since it was not based on adequate knowledge. The first great milestone in modern genetics was the announcement by Camerarius of Germany in 1694 that plants reproduce by the union of male and female cells. This suggested deliberately uniting two different kinds of plants and was followed by the hybridization work of Fairchild in England about 1717, and of many others after him. It was not long (1727) before hybridization was put to commercial use by the Vilmorins in France, and by 1840 they were actually using a kind of progeny test. In 1859 Darwin put biological science on an experimental basis with his Origin of Species, and in 1866 Mendel in Austria worked out the mathematical laws of dominance, recessiveness, and segregation, previously observed but not interpreted by other workers. Mendel's paper remained unnoticed for many years, but meanwhile others were hot on the trail of the same conclusions. When his work was rediscovered in 1900, it gave a tremendous impetus to research and practical breeding alike. Shortly after this (1902–03), the observed phenomena of heredity were definitely and finally linked with activities within the cell.

The development of knowledge of the cell goes back at least to the time of Leeuwenhoek in the Netherlands, who first discovered the world of the microscope (around 1677). In 1838–39, Schleiden and Schwann in Germany generalized that all bodies are made up of cells;

138904°—37——12

10 years later Hoffmeister in Germany actually saw chromosomes. In 1864, Nägeli in Switzerland was attributing the control of heredity to solid particles in the cell—an idea finally clinched by Weismann in 1892, after Haeckel, Strassburger, Flemming, Von Beneden, and others had developed more knowledge of the cell nucleus. From this time on the study of chromosome phenomena proceeded rapidly through the work of many cytologists, up to our own day when genes are accepted as the basis of inheritance and more and more of the facts of heredity are being checked against observed happenings in the cell nucleus. These developments have contributed also to an understanding of animal breeding, which on the practical side goes back through the work of Bakewell, the Collings, and others of a century ago, to Mago the Carthaginian, who in pre-Christian times developed the first known score card for livestock judging. Without mathematics, much of this knowledge would be unusable, and the work of many mathematicians has contributed to the exact interpretation of phenomena and to the practical application of theory.

Outstanding among recent developments are the identification of hundreds of genes in various organisms; the "mapping" of genes on chromosomes by genetic studies, and cytological proof of the actuality of these concepts; the use of the pomace fly for extremely fruitful genetic investigations; an understanding of many complex gene interactions that modify the original Mendelian laws; an increasing body of knowledge about chromosome behavior, which promises to open up new possibilities of practical control in breeding; and the beginnings of knowledge, through the use of X-rays and other forms of wave energy, of how basic changes in genes and chromosomes are brought about, so that controlled genetic change becomes a speculative possibility.

The most recent developments indicate that new researches in biological chemistry may in their turn throw light on some of the many unsolved secrets of the gene and its control of heredity.

VEGETABLE CROP BREEDING AND IMPROVEMENT—AN INTRODUCTION

VICTOR R. BOSWELL, Principal Horticulturist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

IN CONTRAST with the comparatively small number of different species of important extensive farm crops—a half dozen cereals, two fiber crops, two sugar crops, and perhaps a dozen forage crops—literally scores of common vegetable-crop species are widely grown over this country. The scientific basis for orderly and efficient breeding of most vegetables is much less highly developed than in the cereal and sugar crops, for example, and therefore less can be said concerning the genetics of most individual vegetable-crop species. Even so, the large number of crops to be considered compels drastic limitation of subject matter and scope of the articles that follow.

FEW FOREIGN VARIETIES ADOPTED IN THE UNITED STATES

THE excellent and comprehensive treatments of wheat, corn, and certain other crops in the 1936 Yearbook of Agriculture include much data upon foreign varieties, breeding, and improvement; but for many of our vegetable crops such information either is not available or is of such limited interest in the United States that its compilation and publication are hardly practicable. In the main, foreign varieties of vegetables either do not appeal to our tastes or are not well adapted to the environment and the methods of handling in the United States. There are noteworthy exceptions, of course, for there is some international agreement in consumers' tastes and a few crops show wide ranges of adaptability. But the activities of foreign workers have thus far remained to a a large extent of academic interest to us, except insofar as they dealt with basic problems of genetics or plant culture. A few examples will explain our limited use of foreign productions.

England stands preeminent in the improvement of the garden pea. More of our pea varieties (or their parent varieties) originated there than in all other countries combined. The English climate is quite cool and moist, ideally adapted to the garden pea, which is sometimes called the English pea. Even though many of our varieties are readily traceable to English work, they constitute only a fraction of the number that have been produced and are still grown in that country. Most of the English varieties are not at all adapted to our more extreme and changeable climate. Most of our own varieties of peas are inferior in quality to the English varieties as these are grown in England.

Tomatoes are grown in England almost exclusively in greenhouses. None of our important commercial sorts will bear satisfactorily out

contribution to vegetable improvement. As has been pointed out for other kinds of crops, they have devised shorter and more effective methods of improvement that are gradually coming into general use by commercial agencies. The Federal and State workers have also accomplished incalculable benefits by the simple procedure of developing superior stocks of old varieties by selection, freeing stocks of mixture and disease, and releasing the resulting material into trade channels. Some of the best and latest productions will not be generally offered for sale for another year or so.

NEW INFLUENCES IN VEGETABLE IMPROVEMENT

Although the avoidance of contamination with disease is perhaps the foremost consideration in seed certification by several States, certification also relates to trueness to varietal type and freedom from rogues and mixtures. This certification does not involve original breeding or improvement but does compel the application of up-to-date methods of maintaining advances that have been made by breeders. Certification, therefore, deserves mention as a public service closely allied with improvement. From a practical standpoint it has resulted in very substantially raising the standards of performances of tens of thousands of acres of vegetable crops.

Under authority of the Bankhead-Jones Act, passed in 1935, the Division of Fruit and Vegetable Crops and Diseases is developing near Charleston, S. C., a well-equipped vegetable breeding laboratory for the study of fundamental breeding problems that are basic to the production of new and improved varieties for the South and Southeast. Solutions to these problems of national and world interest will of course be forthcoming. Rapid progress is being made in providing facilities for research, and a small but able and active staff has been at work since the spring of 1936. The establishment of this station, the only one in this country devoted exclusively to vegetable breeding, is a particularly significant step, but is only one of the signs of the times. The study and application of genetics are certain to solve an increasing number of our problems and contribute greatly to the general welfare.

Another station in the United States that may well be expected to make unusual contributions is the Great Plains Horticultural Field Station, of the Division of Fruit and Vegetable Crops and Diseases, at Cheyenne, Wyo. A most extensive collection of thousands of domestic and foreign varieties, strains, and stocks of vegetables has been acquired by that station in the quest for characteristics of earliness, drought resistance, and cold resistance. Vast stretches of our western United States have such a short growing season by reason of high latitude or altitude, and such extremes of temperature, with low humidity, drying winds, and short water supply, that only a very meager list of vegetable varieties can be grown. There is pressing need for either introducing or breeding varieties of nearly all crops for home and local market use by people living in those areas. The staff of the station at Cheyenne includes men highly trained in horticulture, genetics, cytology, and physiology. The joint efforts of all are directed to the examination of promising material and the execution of a breeding program designed to meet the requirements of the region.

The Division of Plant Exploration and Introduction of the Bureau of Plant Industry plays an important part in the breeding programs, not only of Federal agencies but of all the State experiment stations that call upon that Division for help. Their information upon the geography of plants, their constant close contacts with investigators and dealers all over the world, their exploring expeditions into obscure places, combine to make available to plant breeders in this country a wealth of the world's plant materials that is remarkable. And naturally the Division assists foreign investigators by supplying in exchange considerable quantities of material from American collections. The world's supply of plant materials is becoming diffused into all countries for anyone to use who will.

PRESENTATION OF SUBJECT MATTER

A FEW words are in order with reference to the organization of subject matter in the articles on vegetable breeding. It is obviously impracticable to treat each crop extensively, therefore crops have been grouped for treatment. Groups are based on botanical and structural similarities in most cases, but a few on the basis of similarity of use or purpose for which they are grown. This grouping has been adopted purely as a matter of convenience in compiling the information or for presenting together crops of related interest regardless of botanical relations. It is not to be considered as a scientific classification. In most cases the authors of the respective articles are now conducting breeding or genetic investigations or have had special breeding experience with the crops under discussion.

It will be noted that the appendix to this group of articles (p. 340) contains data on a number of unclassified crops not discussed in detail in the articles, such as peanuts, sweetpotatoes, and others. Definite information on the breeding, improvement, and genetics of these crops is indeed meager despite the great economic importance of some of them. There is practically no exact knowledge about inheritance in the sweetpotato, and even the origin of surprisingly few sorts is known. The peanut until quite recently has been almost ignored by scientific breeders and students of genetics, but it is due for increasing attention.

IMPROVEMENT AND GENETICS OF TOMATOES, PEPPERS, AND EGGPLANT

VICTOR R. BOSWELL, Principal Horticulturist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

TOMATO

INSOFAR as we are able to tell from written record, the tomato is a very new crop (*18*).[1] The oldest records of it date back less than 400 years, a brief time when compared with the oldest available records of many other crops. The tomato is of tropical American origin, and early reports indicate that it was planted in maize fields and eaten by the ancient Mexicans, who called it tomati. Apparently it attained no very important place in the lives of those people, perhaps on account of the highly perishable nature of the edible fruit and the absence of known means for its preservation. Although it is believed to be native to the same regions as certain early forms of maize, there are no known prehistoric remains, no prehistoric sculpture or ceramics to record its early culture as in the case of maize, kidney beans, lima beans, and squash in North America, or wheat and numerous other plants in the East. We thus are able to form no definite idea of its antiquity and early importance. The absence of record or remains of plant parts might imply relative unimportance and little use. On the other hand, the earliest references in the literature describe essentially the same forms that are grown today. No new markedly different fruit types are known to have appeared since, and the large forms have never been found truly wild. It is therefore believed that the tomato was already improved far beyond the wild state when North America was discovered. Even so, our smooth, large, symmetrical-fruited varieties of today are in marked contrast to the rough, variable types known in this country a century ago.

We have all heard how the able, up-and-coming young man is rarely appreciated in his native environment but must go abroad to make good, and then returns to receive the approval of his countrymen. Some of our native American crops, including the tomato, have gone through a similar experience. The potato, native to the New World, is called "Irish potato" because colonial America repatriated it to the New World from Ireland, where it had become a very important crop while it was being ignored close to its native land. The tomato was introduced into Europe early in the sixteenth century and became widely distributed. In the seventeenth century it was grown in England for ornament only, although it was known to be eaten elsewhere. By the end of the eighteenth century it was grown

[1] Italic numbers in parentheses refer to Literature Cited, p. 204.

on a field scale in Italy and used extensively as food, but it was a half century more before people in the United States generally dared to eat it.

Early Varietal Adaptation

Although each of several countries in which tomatoes are grown to any large extent usually has a number of varieties that show a considerable range in varietal characteristics among themselves, the group of varieties grown in each region is rather distinct from those grown in certain other parts of the world. Not every country has its own distinct general type, but there are marked differences between geographic areas. It is probable that definite selection and breeding work with the tomato for adapting it to warm-temperate and cool-temperate regions has been in progress but a short time, not over two centuries and perhaps only half that. Nevertheless, in a certainly brief span this tropical or subtropical plant has been adapted to a wide range of environments far different from its native home. The efforts at selection by early growers of the crop together with natural factors produced a very interesting and effective assortment of general types, each of which apparently points toward the maximum adaptability in each region.

The best Italian varieties in general are of long season and are large, vigorous growers, with a profusion of thick-walled fruits of unusually brilliant color and high content of solids. A wide range in fruit size exists among these varieties, some of the most valuable being small, as judged by United States preferences. The important point is that those varieties do better in Italy than elsewhere and are better for Italian purposes than others that have been tried in Italy.

There is a considerable outdoor culture of tomatoes in Germany and some adjacent north-European areas. The varieties grown there are early, relatively small-vined, and medium- to small-fruited.

THE *early tomato breeders did excellent work in producing plants with good yields of large handsome fruits, adapted to local or regional conditions; but the situation has changed, and new problems and requirements have arisen so fast that it is not now possible to keep ahead of them by the old method of selecting chance variants in the field. Systematic effort is necessary to find and bring together characteristics that will make entirely new varieties resistant to specific diseases and to heat and cold, and adaptable to long-distance shipment, to new areas of culture, to new processes or means of utilization. This is the kind of work being done by State and Federal agencies. The disease problem especially is so important today that practically no research agency would introduce any new variety unless it were resistant to at least one very troublesome disease.*

Italian and most United States varieties are not adapted to the climate of Germany, and the German varieties when grown in the United States are distinctly inferior to our own. Except for color differences, the north-European sorts are largely of the one general type described.

As mentioned in the introductory article on vegetables, the English have developed a characteristic type of greenhouse tomato, some varieties of which are practically parthenocarpic, requiring no pollination, by hand or otherwise, as American varieties do, in order to set fruit. These varieties are very prolific, setting very large numbers of fruits that are too small to suit American growers and consumers—but they are well adapted to the region and to the purpose for which they are grown. They were the first improved varieties in the modern sense.

In a large country like the United States, with a climatic range from subtropical to cool temperate and from humid to arid, different variety groups have been developed to suit different parts of the country. Until about 10 years ago most of this adaptation had been effected by private growers and seedsmen, who selected chance variants or the progeny of natural crosses that were particularly promising in a given region. A few of the old important varieties were the results of artificial hybridizing. Extensive commercial tomato production in this country is not much over 50 years old. Sixty years ago the only large sorts were rough, ugly, heavily ribbed, variable "varieties" of indifferent quality, although some good small ones of the greenhouse type had been brought in from England.

The old varieties were certainly quite heterozygous or mixed in their hereditary composition, for the tomato frequently crosses naturally in the field. Bailey (*3*) and others have referred to tomato varieties running out. These cases were doubtless due to the effects of more or less accidental selection within very mixed populations. These few rough and ready mixtures, our early so-called varieties, were the confused mass of raw material from which so many of our really good varieties have been selected, directly or indirectly, by keen-eyed growers. Tomatoes are now grown commercially in every State in this country.

Improvement in the United States, 1850–1910 [2]

Prior to 1860 no tomato varieties had been developed in the United States. The few varieties known had been brought in chiefly from England and a few from France. It appears that most of the large-fruited varieties, if not all of them, had been obtained by selection from the old Large Red or ribbed type that had been known since about 1550. The smaller fruited, more prolific forcing or greenhouse types and similar sorts presumably were first selected from the round tomato (smooth), which was originally described by Tournefort about 1700. Since there has been only a minor interest in the small-fruited forms in this country, a chronology of tomato improvement will be confined largely to the story of the old Large Red and its descen-

[2] In the preparation of this historical review the writer has freely used unpublished notes and records in the files of the Division of Fruit and Vegetable Crops and Diseases made by the late W. W. Tracy, Sr., and by D. N. Shoemaker and other former staff members.

dants. The old Round, however, has apparently contributed some genes of value. The cherry-, pear-, and plum-shaped tomatoes have been known as long as the Large Red but have undergone no appreciable change.

Probably the first true dwarf or "tree" variety, named Tree, was introduced by Vilmorin-Andrieux & Cie., of Paris, in 1860, and was promptly brought into this country. It was found as a chance variant in a tall variety by a private gardener of an estate at Chateau de Laye in France. Two other imported varieties of interest in the United States, introduced about that time, were Fiji Island (1862) and Cook Favorite (1864). Several forcing types of European origin were being grown, but their origin is obscure.

Probably the first United States contribution to tomato improvement was the introduction of the Tilden variety by Henry Tilden, of Davenport, Iowa, in 1865. It originated as a chance seedling in a field of a variety the name of which is not recorded (*3*).

The next notable advance occurred in 1870 with the introduction of Trophy, a result of hybridization and selection by a Dr. Hand, of Baltimore County, Md. It is said to have been from a cross of Large Red × Early Red Smooth. The variety was introduced by G. E. Waring, of Newport, R. I., who received it as a supposedly fairly well-fixed stock from T. J. Hand, the son of the originator. It has been stated that Trophy was involved in the parentage of most of the varieties introduced in the following quarter century, and undoubtedly it has contributed, at least indirectly, to a great number of later varieties. The old original Trophy was evidently not very well fixed, however, for before 1900 it had practically ceased to exist (*3*). Through both purposeful and accidental hybridization, and through artificial selection and natural selection within a rather heterozygous variety, superior variants were saved and inferior ones discarded. There is evidence, too, that the perpetuation and increase of undesirable variants appearing in the variety (running out) as a result of segregation, natural crossing, mechanical mixture, or combinations of these, hastened the demise of the variety.

Figure 1.—A. W. Livingston (1822–98), pioneer tomato breeder of Columbus, Ohio, who developed many tomato varieties still in current use.

The work of A. W. Livingston (fig. 1), of Columbus, Ohio, and his associates and successors in the Livingston Seed Co. has resulted in the introduction of more new varieties than that of any other private group. Most of the varieties introduced by the Livingstons were of their own

finding or origination, but some were obtained from other growers. Paragon, from a chance seedling, was their first introduction (1870).

The famous old variety Acme was developed by A. W. Livingston from a single superior plant found in a field of mixed stock and introduced in 1875. Like the Trophy, this variety was the source or served as one parent of many subsequently introduced varieties. In 1880 Perfection, a chance variant in Acme, was introduced. Livingston next brought out Golden Queen in 1882, Favorite in 1883, Beauty in 1886, Potato Leaf in 1887, Stone (4) in 1889, and Royal Red in 1892. This last was developed from seven similar plants found in a field of Dwarf Champion by M. M. Miesse. The others just named were chance seedlings occurring in varieties the names of which are not known. These were followed by Aristocrat and Buckeye State in 1893, Honor Bright in 1897, and Magnus in 1900, as chance seedlings in varieties not recorded. In 1903 Dwarf Stone was introduced; it was a chance seedling found in Stone. Globe (4) is from a cross between Stone and Ponderosa made about 1899 by Robert Livingston and was introduced in 1905. Hummer, another introduction, was selected out of Paragon.

Of this impressive list introduced by the Livingstons, Stone and Globe are among the most important varieties grown today. Acme, Beauty, Buckeye State, Dwarf Stone, Golden Queen, and Perfection are still listed by some seed producers although they are not extensively grown.

In 1882 D. M. Ferry & Co. obtained a selection made by a farmer grower from an unknown variety, and they introduced it in 1885 as Optimus.

Some introductions of W. Atlee Burpee & Co. were Matchless, introduced in 1889; Fordhook Fancy, a production by E. C. Green, of the Ohio Agricultural Experiment Station, in 1898; Combination (Lorillard × Acme × Comet) in 1896; and Quarter Century in 1899—a cross between Lorillard and Dwarf Champion. These last two were developed by Walter Van Fleet, then of the Rural New Yorker.

In 1887, at the Michigan Agricultural College, L. H. Bailey selected a single outstanding plant from a plot of a German variety, Eiformig Dauer. This was released as the Ignotum variety and proved to be of major importance for many years.

Several varieties that had attained importance prior to 1910 are either of obscure parentage or their parentage has been reported and the introducer's name is not definitely known. Lorillard, named for its producer, was introduced in 1888 and was said to be from a cross between Acme and Perfection. The following are of unknown parentage: Chalk Early Jewel, by Moore & Simon in 1900; Ponderosa, by Peter Henderson in 1891; Early Detroit (4), from seed obtained from a Mr. Rosendahl, of Fort Leavenworth, Kans., introduced in 1909 by D. M. Ferry & Co.

The Stone variety has been the supposed parent stock of several varieties of considerable importance, among them Dwarf Stone, mentioned above; Earliana (4), found by George Sparks, of Salem, N. J., and introduced in 1900 by Johnson & Stokes; Greater Baltimore (4), found by John Baer, of Baltimore, Md., and introduced by J. Bolgiano & Sons in 1905.

Johnson & Stokes introduced Bonny Best (*4*) in 1908. It came from a single plant selection in a field of Chalk Early Jewel by G. W. Middleton, of Jeffersonville, Pa.

With all due credit to the important contributions of other growers seedsmen, and investigators, it is not out of place to call attention again to the great contribution of the Livingston Seed Co. to tomato improvement. Of about 40 varieties that had attained a distinct status prior to 1910, a third were productions of or introductions by the Livingston company. If we add those varieties derived directly from Livingston productions and introductions, it appears that half of the major varieties were due to the abilities of the Livingstons to evaluate and perpetuate superior material in the tomato.

Private Introductions, 1910–36

Due credit must be given the early workers mentioned in the preceding pages. Their object was to get good yields of large handsome fruits borne by plants adapted to local or regional conditions, and they succeeded admirably—so well, in fact, that about half of the 40 important varieties known in 1903 are still listed by at least a few of the larger producers and dealers. A few varieties, notably Chalk Early Jewel, Earliana, Ponderosa, Stone, and the dwarf sorts are universally listed. This older type of effort still continues, and from time to time some quite worth-while strains result from it. In comparison with the period 1875 to 1900, however, the old method of selection and crossing among present commercial sorts has in recent years resulted in a smaller number of marked improvements. Many of those obtained have been of value, particularly with respect to regional adaptation and suitability for long-distance shipping or for manufacture.

The Cooper Special, a variety with a distinctive, determinate, or "self-topping" habit of vine growth, was introduced by C. D. Cooper, a farmer near Fort Lauderdale, Fla. It was found as a chance seedling by Bert Croft in Florida in 1914.

Grand Rapids Forcing, long a popular greenhouse variety, was produced by John Nellist, a grower near Grand Rapids, Mich., by crossing Bonny Best and Comet, an English variety.

In 1915 John Baer, of Baltimore County, Md., turned over a selection from Bonny Best, which was named John Baer, to J. Bolgiano & Sons for introduction. Although similar to Bonny Best in many respects, this strain or variety seems particularly adapted to the northeastern group of tomato-growing States and is often preferred to other stocks offered under the name of Bonny Best.

In 1920 the Everett B. Clark Seed Co. introduced an early shipping variety, named Clark Early, for culture mainly in the South. It was obtained by selection. D. M. Ferry & Co. in 1921 introduced Gulf State Market, a variety very similar to Globe but a trifle earlier in the South and less susceptible to cracking. It was found as a single plant in a field of Early Detroit by Walter Richards, of Crystal Springs, Miss., in 1917.

The J. T. D. is an interesting example of a local type developed for adaptation to a specific set of conditions and needs. It was developed

by the Campbell Soup Co. for growing in New Jersey, mainly for its own factory use. It has not become widely grown elsewhere.

In addition to these rather distinct sorts, several commercial firms and seed growers have given special attention to the isolation of superior stocks and strains of a number of the leading commercial varieties. Some of these stocks have been introduced under new names but frequently with only slight variation in the accepted name. A new name or a modified name does not, of course, insure improvement or even a difference. It may fairly be stated, however, that a number of these carefully handled "special" commercial strains of well-established varieties have proved to be superior to stocks generally available under the common name.

Improvement by Public Agencies

A discussion of the research that makes possible more rapid and orderly improvement of the tomato will be found in the section on Studies of Inheritance and Cytology at the end of this article. At this point will be presented a historical review of the new varieties introduced by State agricultural experiment stations and the United States Department of Agriculture.

In the last 25 years new problems and requirements have arisen so fast that tomato breeders cannot find naturally occurring chance variants with the desired characteristics fast enough to keep ahead of requirements. Special efforts are necessary to find and bring together these newly required features to produce new combinations, entirely new and different varieties. Of course the old objectives of large, smooth, high-quality fruit and high yields are still sought, but they must be in combination with such factors as tolerance or resistance to specific diseases, to heat, to cold, and adaptability to long-distance shipment, to new areas of culture, and to new processes or means of utilization. These characteristics are difficult to find and combine quickly with other desired properties.

Introductions prior to 1910 by public agencies were few and far between. Reference has already been made to Ignotum, selected by Bailey at the Michigan Agricultural College, and Fordhook Fancy, produced by Green at the Ohio station.

The major part of the tomato breeding by State and Federal agencies has been done in efforts to develop varieties resistant to disease. Thus far most attention has been devoted to resistance to fusarium wilt (fig. 2), but resistance to other diseases has also been sought, namely, nailhead rust, leaf spot, leaf mold, mosaic, and curly top. The disease problem in general has become so important that today there is little inclination on the part of research agencies to introduce any new tomato variety unless it is resistant to at least one very troublesome disease.

Selection for resistance to fusarium wilt was first started in 1910 by Essary (*15*), of the Tennessee Agricultural Experiment Station, and by Edgerton (*13*), of the Louisiana station. Two years later Essary distributed a resistant strain of the general type of Beauty but with a scarlet fruit like the color of Stone. This new sort, developed by mass selection from a diseased field near Gibson, Tenn., became known as

Tennessee Red. Later Essary distributed a wilt-resistant variety with scarlet-red fruit, named Tennessee Pink, also developed by mass selection in seriously diseased fields. Edgerton, in Louisiana, announced his first wilt-resistant sort in 1912. It was called Louisiana Wilt Resistant and was developed from a single resistant plant selected in a badly infected field of Acme.

Although Louisiana Wilt Resistant proved highly resistant to the disease, it was late and a poor yielder. Edgerton crossed it in 1912 with the Langdon strain of Earliana to get earliness and fruitfulness. From the progeny of this hybrid a scarlet and a scarlet-red strain—

Figure 2.—A comparison of wilt-susceptible (*A*) and wilt-resistant (*B*) varieties of tomatoes on heavily infected land.

commonly called "red" and "pink", respectively—were isolated, named Louisiana Red and Louisiana Pink, and distributed about 1918.

Norton (*40*), of the Maryland station, began selection for wilt resistance in 1912, selecting from a large number of varieties grown near Preston, Md., on a field naturally heavily infected. A number of unnamed resistant selections were distributed in 1915 to tomato growers and investigators. One of these, a wilt-resistant strain of Greater Baltimore, was further selected and grown for seed for several years by O. W. Twilley, of Hurlock, Md. In 1912 Norton selected a wilt-resistant sort from a field of badly damaged mixed varieties near Vienna, Md. This was included among strains given in 1915 to F. J. Pritchard (fig. 3), of the Department of Agriculture, who started his disease-resistant improvement work in that year. Two years of fur-

ther selection in this strain by Pritchard resulted in the Norton variety, distributed in 1917 by the Department and named for the man who made the original resistant plant selection. Two other resistant strains that Norton gave to Pritchard in 1915 were selected by the former from fields of Greater Baltimore. Pritchard selected them further under conditions of heavily artificially infected soil and distributed them in 1918 under the names of Columbia and Arlington. These three varieties, Norton, Columbia, and Arlington (*42*), developed by the informal joint efforts of the Maryland Agricultural Experiment Station and Department workers, were widely disseminated and were the leading resistant varieties, particularly in the East, for some years.

Pritchard distributed a third improvement in 1918 under the name of Marvel. He obtained it by selection from a French variety, Merveille des Marchés (Marvel of the Market), which shows a rather high and fairly uniform resistance (*42*).

Figure 3.—F. J. Pritchard, of the United States Department of Agriculture, who did notable work in breeding improved disease-resistant varieties of tomatoes.

Since 1917 the wilt-resistant varieties produced by the Department have greatly predominated over those originated by others. For reasons not entirely clear, those produced by various State experiment stations have remained more or less localized, and the total acreages of them are not very great. It may be that in the course of production and testing the limited opportunities of determining wide adaptability resulted in selections that were especially adapted to a rather narrow range of conditions; or it may be that the larger resources of the Department made possible not only more extensive tests but larger supplies of seed for original distribution and more effective dissemination of information about the new sorts. It seems probable that some of the State work has resulted in varieties quite the equal of the Department sorts now commonly grown, or even superior to them in some respects, but still the latter dominate the field.

It should be recognized here that some of the first stocks of certain Department varieties distributed were the result of massing a number of selections that were apparently similar under the conditions of selecting. Under other growth conditions, undesirable variations in fruit and plant form appeared. Numerous State and private agencies have contributed to the success of these varieties by careful roguing or selection within the early stocks, keeping them in closer conformity to the ideals for the respective sorts.

In 1922 Pritchard introduced Norduke, a cross (Norton × Duke of York) between two resistant sorts. Marvana (Marvel × Earliana) and Marvelosa (Marvel × Ponderosa) followed in 1924. All these earlier introductions by the Department are still listed by commercial firms (most firms list only one or a few of them), but they are unimportant and are not generally grown except in certain localities. Subsequent superior productions have largely displaced them.

The Marglobe (*4*), introduced by Pritchard and Porte in 1925, is without doubt the most important variety of tomato in the United States and in the world today. Its range of adaptability to both environmental and utilitarian requirements and its dominant position have been surprising. Marglobe is the result of a cross between Globe and Marvel made in a greenhouse of the Department in Washington in 1918. Globe has considerable resistance to wilt but is very susceptible to nailhead rust. Marvel is highly resistant to both. Marglobe proved highly resistant to wilt under most conditions and to nailhead under all conditions of which there is record. It was introduced just in time to save the Florida tomato-shipping industry from virtual extinction through the ravages of nailhead and wilt. It was developed primarily as a shipping tomato, but it has turned out to be the principal canning variety in the Middle Atlantic and South Atlantic States, as well as the leading shipping variety of the whole Atlantic region. It was the dominant variety in Mexico during the heyday of the tomato-shipping industry in that country; it is one of the best varieties recommended in Australia, and it is currently listed by commercial vegetable seedsmen in many foreign countries. The Marglobe has been to the present generation what Trophy and Acme were two generations ago. But ultimately, perhaps before long, it will be superseded by still better sorts, for, like all varieties, it has its limitations. It cracks rather badly, particularly in the Middle West, and it is not appreciably resistant to a number of diseases that are becoming increasingly important.

Three more recent productions by Pritchard and Porte should be mentioned before returning to some of the earlier work of the State stations. Marglobe was a parent in two of these—Break o' Day (Marglobe × Marvana), introduced in 1931, and Pritchard [3] (Cooper Special × Marglobe), introduced in 1932. Break o' Day was received much more enthusiastically than Pritchard, as a result of preliminary trials; but it has subsequently slipped into a relatively unimportant place, largely because it fails to meet rigid color requirements under most conditions. Pritchard, however, has become very popular on account of its superior scarlet color, despite the fact that it tends to bear most of its crop in a short time. It was expected to be of no value to canners because of this habit, but it is being used more each year. The third variety, Glovel [4] (Globe × Marvel), is a "sister" to Marglobe but is scarlet-red ("pink") instead of scarlet ("red"). It is otherwise rather similar to Marglobe and is especially interesting because it cracks much less than Marglobe. Although reports on it

[3] Introduced under the name of Scarlet Topper. Renamed Pritchard in 1932 after Pritchard's death in January 1931.

[4] Produced in cooperation with the Florida Agricultural Experiment Station.

are generally good, it is too early to determine its value, since it was introduced in the spring of 1935 and first grown commercially in 1936. These last three varieties are all resistant to both fusarium wilt and nailhead.

The most important variety in the middle-western canning area of Illinois and Indiana is the Indiana Baltimore, developed by the Indiana Agricultural Experiment Station by selection from Greater Baltimore and distributed in 1919. It represents a distinct improvement over its parent variety, although the casual observer would consider it similar.

Yeager (*54*), of North Dakota, has done some of the most interesting tomato breeding in this country, but his work is not generally known and appreciated outside the northern Great Plains area. Yeager has bent his efforts to the development of a list of varieties adapted to a short, rather dry season in a region of wide extremes of temperature and frequent desiccating winds. These conditions are decidedly unfavorable for tomatoes in general. It is only in the last 12 years that farmers and gardeners of the northern Great Plains have had varieties that could be grown there with any satisfaction, but now they have several. Even though these varieties from the North Dakota station are adapted to the area in question and are far better there than anything heretofore available, they are of little interest elsewhere. The very characters that enable them to succeed in North Dakota appear valueless, for example, in Virginia. That, however, is no discredit to the varieties or the introducer. They serve the purpose for which they were bred, and that is enough.

The seven varieties introduced by Yeager up to this time are all early and bear their moderate crops on comparatively small plants in a short time. This is necessary in order to meet the requirements of the region. All were developed by hybridization, one of them involving an interspecies cross. Red River (Earliana × Sunrise), introduced in 1925, and Bison (Red River × Cooper Special), introduced in 1929, are the best known and most important thus far. The latter has shown an appreciable resistance to heat. Two yellow varieties, Fargo Yellow Pear (Bison × Yellow Pear) and Golden Bison (Bison × Golden Queen), introduced in 1932, meet the requirements of those gardeners who desire yellow-fruited sorts. Farthest North is of particular interest because of its parentage (Bison × Red Currant) and its extreme earliness. It was introduced in 1934, so it may be rather too new to tell how important it is going to be. The other two of Yeager's introductions are Early Jumbo (June Pink × Globe), distributed in 1929, and Pink Heart (Bison × Ohio Red), distributed in 1932.

The Santa Clara (*4*) tomato, which is now the principal variety grown for canning in California, is the result of work by several agencies and men. It traces back to a single plant selection made in 1923 by a representative of the Canners League, in a field of a variety called Trophy or Canner. This was not the old original Trophy previously mentioned, nor even the variety generally cataloged under that name by seedsmen. It was a large, irregular, rough-fruited sort that was wasteful and difficult to prepare for canning on account of corrugations

and catfaces, and was grown only for canning in that section. The Canners League, the Ferry-Morse Seed Co., the California Packing Corporation, and the California Agricultural Experiment Station all contributed to the further selection and final development of this huge, moderately smooth-fruited variety that entered into commercial production about 1926. It has a very large heavy-yielding plant that produces the largest fruits of any of the extensively grown commercial sorts, but anyone who tries to grow it east of the Rocky Mountains will be disappointed in it. It is excellent in parts of California but almost a failure in other parts of the country.

In 1928 the California station released a selection from Santa Clara developed through careful inbreeding and called California 55. It was produced for its smoother fruits, high yield, and more intense red color.

The Illinois, Massachusetts, and Michigan stations have placed emphasis on greenhouse sorts because of the magnitude of the forcing industry in their States. In 1930 Illinois introduced Lloyd Forcing and Blair Forcing, both derived from Louisiana Pink × Grand Rapids. Both varieties are wilt resistant. In 1931 Massachusetts introduced Waltham Forcing, a selection from an unknown sort for adaptation to adverse northern greenhouse conditions.

The New Jersey station distributed the Rutgers variety in 1934. It is a cross of Marglobe × J. T. D. and has been reported especially valuable on the light sandy soils of New Jersey. The Illinois station has just released sorts that will set fruit and not grow out of bounds on the high-nitrogen praire soils of Illinois. The Washington (State) station introduced in 1930 Seedling 36 and Seedling 50, results of crossing Bonny Best × Best of All to obtain higher productivity under Washington conditions. They were intended to be adapted to a specific environment, hence it is not surprising that they have remained of rather local interest.

Within the last year or two many stations have released several additional strains and varieties that may or may not make important places for themselves. Small plot tests, even though numerous and fairly widespread, often fail—in fact usually fail—to reveal the true commercial possibilities of a new line and to indicate the reactions of the tomato-growing industry and the consuming public. Only time and general commercial trial can determine these things. The newer introductions, as reported by their originators, are listed in table 4 of the appendix to the vegetable articles, along with those discussed in this brief survey.

Gratifying progress has been made in the selection of verticillium and fusarium wilt resistant strains of tomato in California by Michael Shapovalov, of the Department, and B. A. Rudolph, of the California station, working cooperatively.

PEPPERS

History

The hot and the sweet peppers grown in the United States belong to a quite different group of plants from the black or white pepper of commerce. The peppers that we grow in this country are *Capsicum*

annuum L., a New World species native to the Tropics. There are no ancient eastern names for the species, and the first record of it (1493) indicates that Columbus took the first specimens to Europe on returning from his first voyage to the West Indies. Peppers or chilis are known to have been one of the principal foods of the native inhabitants of tropical America. The pepper had already reached a fairly modern state of improvement at the time of its discovery by Europeans, as evidenced by the wide diversity of the several distinct sorts described in the early records. All the types current today were known to be used by the natives of Central America in the seventeenth century (*18*). It would thus seem that the prehistory of the pepper might closely parallel that of the tomato.

There seems to have been no such aversion in Europe and colonial America to the use of peppers as there was to tomatoes. Peppers were apparently adopted immediately, and their use quickly became almost worldwide. Certain types became established so promptly in India, for example, that some of the early botanists believed them native to the East. However, the name "chili", which is still used in India, strongly indicates importation from South America.

Although they were quickly adopted and have been generally used beyond their native land for over 400 years, the properties of most varieties of peppers do not make them a product to be eaten in large quantities as a staple vegetable by most users. Generally peppers, even the sweet or nonpungent varieties, form a small proportion of salads or mixed vegetable dishes. Some nationalities, however, use them more or less "straight", the Mexicans in particular consuming almost incredible quantities of them. And those who are familiar with Mexican cookery know how generously the fiery varieties are used.

Improvement in the United States

Since the pepper is not a major crop, it has received far less attention than its relation the tomato. Even though a few enthusiasts have effected some excellent improvements, the importance of the crop itself has not been great enough to attract much attention to more than a few of the advances made. As a result, the records concerning early improvement are very sketchy and incomplete. Unfortunately, no such dependable varietal history can be written for this crop as for the tomato.

In 1901 American seedsmen listed between 125 and 150 varietal names of peppers in their catalogs. Of this number only 18 to 20 probably denoted really distinct varieties, the others being merely synonyms or cases of misnaming. The history of those varieties, with few exceptions, is indeed obscure. It is noteworthy, however, that after 35 years these distinct sorts are all still available commercially with one or two possible exceptions. Furthermore, there have been few very distinct or very marked improvements in type. Many new names have appeared for old forms, and the old stocks have been improved in uniformity and conformity to type. The principal other improvements made have been in securing somewhat thicker flesh and increased earliness. These improvements have been effected almost entirely by private agencies.

The list of practically all really distinct sorts noted by Tracy (*46, 47*) follows:

Pungent varieties—	Mild varieties—
Bird's Eye	Bellior Bull Nose
Cayenne	Black Nubian
Celestial	Chinese Giant
Cherry	Golden Dawn
Large Red Chili (or Mexican)	Golden Giant
Red Cluster	Monstrous (or Grossum)
Small Chili (Red Chili)	Ruby King
Tabasco	Squash or Tomato
Yellow Cayenne	Sweet Mountain
Yellow Cherry	

Until recently most of the hot varieties were the same as when they were first found by Europeans over 400 years ago. One type, however, has been a subject for improvement since about 1900. The large, long, hot type variously known as a Cayenne or Mexican type, or just as plain Chili, is a very important vegetable in the Southwest. This should not be confused with either the very hot Cayenne variety or the very hot small Chili pepper that is used in making pepper sauce. It is a large elongate sort that is eaten green or ripe and used fresh, canned, or dried.

In 1903 Musser (*14*) introduced Anaheim Chili, named for the town of Anaheim, Calif., an important center of production and drying of this type of pepper. It was developed by mass selection from the Mexican Chili for longer, thicker-fleshed pods. It is still an important variety.

About 1917 Garcia (*16*), of the New Mexico Agricultural Experiment Station, introduced Chili No. 9, also a selection from the native Mexican type. He selected specifically for larger size, thicker flesh, a sloping shoulder to facilitate peeling, productivity, and general adaptability to canning under New Mexico conditions. Incidentally, he obtained an intermediate resistance to fusarium wilt. The strain has replaced most of the older ones grown in the warmer parts of New Mexico.

Recently, by pure-line selection, Miller, of the Louisiana station, has developed a number of highly uniform, intensely colored, productive strains of very hot peppers of the Tabasco and Cayenne types. The production of Tabasco peppers for making Tabasco pepper sauces is an important industry in Louisiana. In 1935 Miller distributed Tabasco 10–1 and Tabasco 10–2. These were developed from the locally grown strains of the variety. Sport was distributed in 1936. It was developed by crossing the local Sport × Honka, an intensely red Japanese variety, then backcrossing to Honka in an effort to further intensify color. A fourth production of Miller's is Selection C–28–11, derived by inbreeding from a locally grown strain, Baton Rouge Cayenne. He selected for superior earliness, greater pungency, yield, and resistance to cercospora leaf spot.

Although the sweet varieties are much more important commercially than the hot varieties, less attention has been given to them by public research agencies in the United States. This is doubtless

because of the keen interest private agencies have shown in the sweet peppers and the very satisfactory contributions they have made.

Two sweet varieties of pepper have been introduced by experiment stations, but so recently that it is impossible now to indicate their probable importance. The Waltham Field Station of the Massachusetts Agricultural Experiment Station introduced Waltham Beauty in 1935. It was selected from an unidentified variety. The Connecticut station introduced Windsor-A in 1936, developed from a hybrid of California Wonder × Bountiful. Both of these new introductions are early, show improved wall thickness, and are adapted to New England conditions.

Practically all of the large-fruited, mild-fleshed varieties were derived by selection or the finding of valuable segregates of natural crosses. The pepper is cross-fertilized to a considerable extent, so that under field conditions natural crosses between varieties may occur frequently. The parent varieties of most of the commercial varieties that have been prominent for the past 50 years are unknown and many of them are relatively old.

As mentioned above, the hot varieties, except for very recent improvements that hardly involve major varietal characters, have been known for 250 to 300 years and even longer. Among the sweet varieties the names of Bell or Bull Nose, Oxheart, and Squash have been current for over 150 years. Most of our present sweet varieties have come from these types. The types were first described about 400 years ago.

Just as the period from 1875 to 1900 was very productive of new introductions and selections of tomato, so it was with peppers. Although many new names and some improved stocks appeared, few really marked advances can be recorded. Many of the supposedly new introductions during that period represented varieties that could be recognized by detailed descriptions in the literature over 200 years old. We may be safe in assuming that nearly all varieties known about 1850 were very old and that about half the "new" varieties introduced between 1875 and 1900 had been known for 100 to 200 years. Table 1 shows only too well the fragmentary nature of our present knowledge of the origin of some of the better known varieties.

There are a few varieties that command special interest. Chinese Giant and Ruby King are doubtless selections out of the old Bell or Bull Nose, and Chinese Giant represents no very great deviation from its supposed parent variety. It is rather late, tends often to be rough, and is only a moderate to shy producer. Ruby King, introduced by Burpee, was a real improvement over the old type, having more attractive, uniform shape, higher productivity, and better quality. The chief claim of Chinese Giant to fame was its size. Ruby Giant and World Beater are two varieties of some importance that were developed from crosses of Chinese Giant and Ruby King. Royal King was selected from Ruby King, and Magnum Dulce, popular for many years, was selected from Chinese Giant. Although the records are incomplete, it appears almost certain that several of the more recent introductions also have been selected from one or the other of these two varieties or from crosses in which one or both were involved. Ruby King is still one of the half dozen most important

sweet varieties and is perhaps more widely grown than any other single variety. California Wonder is considered the most important improvement in many years, on account of its large size, attractive form, uniformity, and very thick, firm flesh. It is rather late, however, and not well adapted to the northern third of the United States. Harris Early Giant, introduced by the Joseph Harris Seed Co., is very popular in the more northerly areas where California Wonder is too late.

TABLE 1.—*Origin of some of the more important pepper varieties of the United States*

Name	Early reference to variety	Varietal history in United States: First described or advertised	Varietal history in United States: Origin
Anaheim Chili		1903	Selected from Mexican Chili by H. J. Musser
Bell (or Bull Nose)	1774	([1])	Precolonial New World
Black Nubian	1733	1991	European variety
California Wonder		1828[2]	Selection by a California grower
Cardinal		1887	
Cayenne	1542	([1])	Supposedly French Guiana
Celestial	1731	1887	Chinese variety
Cherry	1586	([1])	Precolonial New World
Chilli (or Chili)	1588	([1])	Do
Chinese Giant		1900[2]	Selection from Bell (?)
Elephant's Trunk		1892	Selection from Cayenne (?
Etna	1640	1890	First advertised by W. Atlee Burpee & Co
Golden Dawn		1882	
Golden Neapolitan		1906	Chance seedling in Neapolitan
Golden Upright		1887	Unknown
Harris Earliest		1920	Introduced by Joseph Harris Seed Co
Kaleidoscope	1632	1890	Precolonial New World
Long Red	1813	([1])	Do
Long Yellow Cayenne	1832	([1])	Do
Magnum Dulce		1904	Selected from Chinese Giant
Monstrous		1867	Selected from Bell (?)
Neapolitan		1903	Italian variety
Nepal Chili	1809	1895	
New Mexico Chili No 9		1917	Selected from Mexican Chili by F. Garcia
Oxheart		1844	
Perfection		1912	Selected from Spanish pimiento by S. D. Riegel
Royal King		1918[2]	Selected from Ruby King by George Riegel
Ruby Giant		1906	Ruby King × Chinese Giant
Ruby King		1884	First listed by W. Atlee Burpee & Co
Squash (or Tomato)	1686	([1])	Precolonial New World
Sunnybrook		1922	Selected from Squash. Introduced by W. Atlee Burpee & Co
Sweet Mountain		1849	Selected from Bell (?)
Tabasco	1888	([1])	Introduced from Mexico
Waltham Beauty		1935	Selection
World Beater		1919	Chinese Giant × Ruby King

[1] Unknown, very old. [2] Approximate date.

The sweet peppers of the Squash or Tomato type are very popular for home garden and local market use, but are relatively unimportant in the heavy commercial shipments. Sunnybrook, introduced by Burpee, is the best known and most important of these. A tempest raged a few years ago in the horticultural press over claims that certain varieties of this group represented hybrids between pepper and tomato. The new names involved in the controversy implied hybrid origin, and the varieties were advertised and sold with the claim that they were new hybrids. However, numerous botanists, horticulturists, and growers who know peppers and tomatoes have never been able to detect any trace of tomato characteristics in either the plant or the fruit. The tomato shape proves nothing, for that

has been known in peppers for about 400 years. Furthermore, tomato and pepper belong to such distantly related genera that crossing the two is believed to be impossible. There is, at least, no convincingly documented case of such a hybrid known, despite the fact that skillful workers have often tried to cross them.

Another interesting varietal development is that of the Perfection pimiento pepper, selected to meet a specific requirement by S. D. Riegel, of Georgia. The introducer of this variety was engaged in the canning of peppers and required a very mild, very thick-fleshed sort having specific qualities of flavor and adaptability to canning. Since no such variety was grown in the United States at that time, he obtained seed of a Spanish pimiento from Spain. The variety name was not stated, but it was probably Sweet Genua or a closely related form. From this Spanish stock a single plant was selected having the desired characters and apparent adaptability to conditions in the southern United States. The variety Perfection was developed by selection from the progeny of this plant and first introduced to the trade about 1912.

EGGPLANT

History

THE eggplant, *Solanum melongena* L., is believed to be native to the Tropics of the Old World. It was referred to in Chinese writings of some 1,500 years ago, and by various early writers in the sixth, ninth, twelfth, and thirteenth centuries (*18*). It appears to have been unknown in Europe in ancient times and is therefore believed to be Asiatic in origin. Vavilov (*48*) has concluded through his botanical-geographic studies that there were two centers of origin, the first in subtropical or tropical India, the second in China.

In the sixteenth century various writers described eggplants of the several colors known today—purple, yellow, white, ash-colored, green, and brownish. The oblong or elongated, pear-shaped, and round forms were also known in that early day. At present there is almost no interest in any but the purple-fruited sorts in the United States, but occasionally other colors are grown for ornament. There is good evidence that no new or distinct types have been developed within historic time, although of course numerous variations or varieties have been found and propagated within each type. It is probable that considerable increase in size has resulted from comparatively modern efforts, because the varieties described early in the seventeenth century seem to have been rather small. A hundred years later descriptions are found indicating fruit sizes that are comparable with our present sorts.

Vilmorin-Andrieux & Cie., Paris (*49*), in 1856 described 7 varieties, including Long Purple, Round Purple, Chinese Long White, Large Purple, and Guadaloupe Striped. Burr (*5*), in this country, in 1865 listed these same varieties as of interest here, and in addition described New York Improved. New York Improved and Long Purple are still among the half-dozen varieties of commercial importance in the United States today.

The eggplant does not have any great appeal to the majority of consumers in this country, so it remains a minor crop—and probably will

so remain for a long time. This general lack of interest is reflected in the small attention it has received here from plant breeders and investigators. There are few varieties grown in the United States, and little is being done to produce new ones. In the Orient, however, the situation is quite different. The eggplant is one of the most important vegetables in China, Japan, and India, holding in those countries a position more nearly comparable with that of the tomato in North America. Because of its extensive use and popularity in the Orient, numerous varieties have been developed and it has been the object of perhaps more genetic and cytological study than in Europe or North America. Numerous oriental varieties have been introduced for trial by American growers and seedsmen but have never attracted interest. Some of them are quite productive, but generally they are of small-fruited types or of colors that do not appeal to us.

Breeding and Improvement

All our important commercial varieties are the result of work by private gardeners and seedsmen. Most of them were doubtless obtained merely by selection from the old long-established types and represent minor improvements except in fruit size and uniformity. Unfortunately we are unable to determine with certainty the time, manner, and place of origin of our present varieties.

The white, striped, and scarlet-fruited sorts are all very old and are of interest only as novelties or ornaments, so they will not be discussed here.

Of the purple-fruited sorts, Round Purple and Long Purple doubtless were imported from Europe a century or more ago. Vilmorin-Andrieux & Cie. (*49*) lists Large Purple as of American origin, introduced in 1854. The parentage is unknown.

Burr (*5*) lists New York Improved, indicating that it was derived from Large Round. It was described as having spiny leaves. It appears that the variety was developed by selection about 1850 by Brill, a gardener and seed grower of Long Island, N. Y., and named by him. The modern strains of New York Improved are spineless. Spineless strains have been available since about 1900.

Black Pekin was a popular variety for many years but is now rarely listed. It was introduced from China about 1870.

Black Beauty appeared about 1900. It is said to have been originated by Ashcraft, a gardener and seed grower of Swedesboro, N. J. There is little question that Black Beauty has been the most popular eggplant variety grown in the United States. The intensely dark-purple, or purplish-black, fruits of medium-large size are very attractive and are largely responsible for its outstanding prominence.

The old Long Purple variety has been the subject of selection for earliness, particularly in the Northern States. Early Long Purple, or simply Long Purple, is the earliest variety commonly grown, but is grown extensively only where earliness is essential.

The most important development since Black Beauty is the Florida High Bush. It was introduced about 1905 by a Florida grower who selected it for its tall upright growth and habit of bearing its fruits well up off the ground. This character is often of considerable im-

portance as an aid in avoiding losses from fruit rots or other damage resulting from contact with the soil.

The agricultural experiment stations of New Hampshire, Rhode Island, and Wisconsin are all working for increased earliness in eggplant to permit its being grown profitably farther north. The Central Experimental Farm of Canada, at Ottawa, has introduced Blackie, a selection smaller and earlier than Black Beauty that is also more productive in the North.

Kakizaki (*25*), in Japan, demonstrated the commercial feasibility of artificially produced hybrid eggplant from inbreds known to be superior for the purpose. In 1931 he introduced Black Bountiful, a first-generation hybrid which has been offered for sale in the United States by Japanese seedsmen. It is distinctly smaller than our well-established sorts and so has not become popular here. However, it is early and very productive.

STUDIES OF INHERITANCE AND CYTOLOGY IN SOLANACEOUS FRUITS[5]

Tomato

The first investigators (*17*, *41*) of the mode of inheritance of specific characters in the tomato quite naturally and logically examined certain of the most obvious features of plant and fruit, such as cotyledon size and shape, leaflet size and shape, leaflet surface character, plant stature, growth habit, fruit color, fruit shape, and internal structure of fruits. Such studies have been made over the last 30 years, but the most conclusive results have been reported in the last 15 years. J. W. MacArthur, at the University of Toronto, and E. W. Lindstrom, at the Iowa Agricultural Experiment Station, are the most active in studying inheritance in "normal" individuals, while J. W. Lesley and M. M. Lesley in California, F. W. Sansome in England, besides Lindstrom, are engaged with cytological studies, induced mutations, polyploidy, and the occurrence of aberrant forms.

A large number of workers have contributed to the present knowledge of inheritance of specific characters in the tomato, but it is not necessary to cite here all the literature of all workers. Table 2 presents a summary of the characters studied to date, with data concerning dominance and indications as to whether the contrasted characters are due to differences in one or more factors. Most of those listed represent single factor differences.

Unfortunately, the characters that we most desire to incorporate into our new varieties to meet new needs cannot be listed in the table at this time. These are resistance to specific diseases, such as fusarium wilt, verticillium wilt, nailhead, leaf mold, septoria, mosaic, streak, and curly top. Although there are many varieties showing a fairly high resistance to fusarium, a few resistant to nailhead, and resistance to leaf mold, nothing certain is known about the number of factors involved in resistance to any of these diseases, and there are only general unconfirmed indications of the dominance or recessiveness of resistance.

[5] This section is written primarily for students or others professionally interested in breeding or genetics.

TABLE 2.—*Inheritance in the tomato*

Characters	Genes	Behavior in F_1	Segregation in F_2	Authority	Tetraploid segregation (after Sansome, *44*)
Flesh color					
Red *v* yellow	*R r*	Red	3 red to 1 yellow	(*17, 29 34 37 41*)	Between 22 1 and 35 1
Red *v* tangerine orange	*T t*	do	3 red to 1 tangerine orange	(*3 37*)	
Skin					
Yellow *v* colorless	*Y y*	Yellow	3 yellow to 1 colorless	(*17, 29 34, 37 41*)	Approximately 35 1
Dark green base *v* uniform green fruit	*U u*	Dark green base	3 dark green to 1 uniform	(*37*)	Approximately 22 1
Smooth *v* pubescent	*P p*	Smooth	3 smooth to 1 pubescent	(*17, 29, 34 37*)

[1] All 6 characters monorecessives, *l* shown to be same character previously known (*32*)

Several difficulties have stood in the way of acquiring this much-needed information. First, strong resistance to certain of these diseases is at present unknown in any form of tomato. Wide search has yielded no appreciable resistance to mosaic, streak, or curly top. And in those cases where a degree of resistance is known, it is usually such an intermediate or partial resistance that it cannot be measured with any dependability. Until methods are developed that will permit accurate determination of the amount of resistance in a plant, under even a single set of reasonably standardized experimental conditions, progress will necessarily be slow. It must be possible to repeat tests with given stocks and get results that will consistently agree if we are to know much about resistance.

Another difficulty is space requirement and cost of conducting such tests with the tomato. Thousands of small-grain plants or peas can be tested on a few square rods of land or a few benches in the greenhouse; but in the field, 15 to 20 square feet is needed for each tomato plant, and 3 to 4 square feet of precious space in the greenhouse. The worker with small plants can test thousands or hundreds of lines where the tomato investigator can handle only hundreds or dozens.

There also has been too much pressure for quick practical results, and many workers have felt it necessary to hurry without being able to make the desirable and often essential preparatory surveys and studies. Now a number of research agencies are backing up for a new start, but they are first carefully preparing to ferret out essential basic information before launching further into practical application of research. It is hardly possible to apply what isn't known.

In his quest for leaf-mold resistance, Alexander (*1*), at the Ohio station, has isolated apparently homozygous resistant lines from segregating progenies of a cross between an off-type resistant plant and the variety Marhio. The off-type plant bore very small fruits on simple inflorescences and appeared to be from a chance cross with the Red Currant variety. Von Sengbush and Loschakowa-Hasenbusch (*45*) have reported that *Solanum racemigerum* Lange (known in the United States as *Lycopersicon pimpinellifolium* Mill.) is completely resistant to leaf mold and that resistance in this species is due to a single dominant factor. They have also reported a recessive form of resistance in the variety Stirling Castle. Alexander's data, although admittedly meager and not taken as part of a genetic study, also indicate a recessive resistance in Stirling Castle and a dominant resistance in Satisfaction, another English greenhouse sort.

D. R. Porter, at the California station, has noted appreciable resistance in *L. pimpinellifolium* to western yellow blight, a virus disease, and is attempting through crossing and backcrossing to incorporate the resistance rapidly into acceptable commercial types. He is also studying the genetics of resistance.

Porte and Wellman, of the Bureau of Plant Industry, found one line of *Lycopersicon pimpinellifolium*, when grown in heavily artificially infected fusarium wilt soil, to be practically immune to wilt and highly resistant to a number of leaf diseases. They used a technique similar to Porter's in order to transfer higher degrees of fusarium resistance to commercial sorts than they commonly carry. By controlled pollination they have also developed a large number of inbred lines of

commercial varieties resistant and susceptible in all degrees. This was preparatory to determining the nature of such disease resistance as the lines possessed, which might be used in further breeding. It has not been possible to observe consistent percentages of resistant and susceptible individuals in repeated tests of a stock or line, or consistent degrees of injury to the plants in repeated inoculation tests. The effects of the texture, moisture, hydrogen-ion concentration, soluble salts, temperature, and fusarium content of the soil, the temperature and humidity of the air, the effect of light, age, and size of plant, and other such factors upon infection and reaction of the plant to the parasite are almost if not entirely unknown. These must be learned and test conditions properly standardized before dependable comparisons of resistance can be made. Special studies are, therefore, in progress in efforts to perfect a technique for dealing with the incomplete type of fusarium resistance, the only type definitely reported to date.

C. M. Tucker, at the Missouri station, has recently reported to the writer that among many seed lots of *Lycopersicon pimpinellifolium* tested, one appears to possess complete dominant resistance to fusarium wilt. Other lots either were 100-percent susceptible or showed the intermediate resistance that is typical of resistant commercial varieties. At this writing his studies have not proceeded far enough to determine more.

A number of other investigators are busy with disease resistance and with selection for improved adaptation to specific requirements, but reports are not now available as a basis for discussing their work. (See list of projects and workers in the Appendix.)

Wellington (*51*) reported yields of F_1 intervarietal hybrid tomatoes about 21 percent higher than the yields of the more productive parent, 45 percent higher than the mean of the two parents, and 71 percent higher than the lower yielding parent.

Linkage in the Tomato

Thus far, the chromosome map of the tomato hardly has its outlines well drawn. MacArthur (*34, 35, 36, 37*) and Lindstrom (*29, 30, 33*) have made the major contributions to knowledge of this problem. Of some 20 genes that are known, the positions of 16 have been located on 10 of the 12 pairs of chromosomes. Six of the groups now contain two or more known genes.

The chromosome map showing the linkage groups and the probable order of the genes within the groups may be represented roughly as follows:

Chromosome	Genes	Chromosome	Genes
I	D_1-*P*-*O* *S* (and genes for earliness ?).	VI	*L* (and genes for earliness and size ?).
II	*R* (?).	VII	*U*-*H*-*T*.
III	B_r-*Y*.	VIII	A_2 (?).
IV	*C*-S_p.	IX	D_2 (?).
V	*F*-A_1-L_f-*J*.	X	W_t *N*.

The second, sixth, eighth, and ninth chromosomes each bear but one known factor.

Currence (*7*) has recently pointed out a relation between genes of the D_1POS region of the first chromosome and genes affecting earliness. The actual nature of the factors involved has not been determined, but *D* and *DP* lines were, on the average, 9 and 14 days earlier respectively than corresponding *d* and *dp* progenies.

MacArthur (*36*) has also recently added evidence of a possible linkage of genes for earliness and size—if there are such—with certain qualitative factors. He showed that *l*, a recessive gene for yellow-green foliage, retards maturity about 2 weeks and reduces fruit size 30 percent. The author recognized that the existence of size and earliness genes linked with *l* was not demonstrated, for the effect might possibly be due directly to *l* or other genes. It is logical to suppose that *l* would have a marked direct effect on plant and fruit development.

It is unfortunate that we do not yet have accurate information regarding inheritance of disease resistance and possible linkages with qualitative genes. Some observations might lead us to suppose that at least certain types of resistance are linked closely with specific characters.

Cytology of the Tomato

Thus far very little if any attention has been given to the cytology of hybrids of *Lycopersicon esculentum* Mill. and related species. The large number of small chromosomes make cytological study quite difficult. In the intensive drive for disease resistance, however, it seems sure that wider and wider crosses will be attempted, with the failures, sterilities, and various aberrations that accompany such efforts. Workers will then find it necessary to study both the normal and the abnormal material cytologically more than has been done in the past.

Most of the cytological work done on the tomato has been in the study of triploids, trisomics, and both natural and artificially induced tetraploids. All three of these chromosomal aberrations occur rather frequently in cultivated fields and may become evident through the departure of the plant from the typical vegetative form and fruitfulness of the variety in which the aberrations appear. A number of these have been described in detail by Lesley (*26*, *27*), Lindstrom (*31*), and others. In general the plants are characterized by a sturdier, stockier appearance; thicker, more rugose leaves; and little or no fruit. They generally produce a large proportion of abortive pollen and may be unfruitful for that reason if not for others.

The normal n number of chromosomes in the tomato is 12, and the $2n$ or somatic number is 24. Aberrant plants have been found with 25, 26, 27 (aneuploids), 36 (triploids), and 48 (tetraploids) somatic chromosomes, and also some with fragments of additional chromosomes. Lesley (*27*) has obtained 12 different simple trisomics, each with a different supernumerary chromosome, by crossing a triploid ($2n=36$) plant with a normal diploid ($2n=24$). He has identified these as Triplo-A, Triplo-B, Triplo-C, etc., depending on which one of the 12 chromosomes occurred as a supernumerary. These identifications of extra chromosomes and the determinations of trisomic ratios in the progenies of hybrid trisomics have afforded additional confirmation of the connection between genes and chromosomes and may add

to knowledge of linkage relations. An understanding of what is happening to the chromosomes of these aberrant plants helps to make it clear why they will not breed true and why it is so difficult, if not impossible, to make practical use of certain desirable characters that some of them have.

Several workers—Winkler (*52*), Jørgensen (*23*), Sansome (*44*), and others—in addition to those already named have induced the formation of tetraploids by cutting off stems of plants. Callus tissue rapidly forms under proper conditions, and in this tissue cells are occasionally formed with 48 instead of 24 chromosomes. Some of these cells may develop into shoots and continue growth in a more or less normal manner. Since these tetraploids are usually nearly sterile or quite so, and since they do not breed true, they are usually propagated vegetatively for experimental purposes. Thus far there is no proved case of a commercially valuable tetraploid.

Lindstrom (*31*) has reported a highly fertile tetraploid of *Lycopersicon pimpinellifolium* obtained from callus tissue, but it is apparently the only such case noted. Some are inclined to believe that the parent plant was not homozygous but that *L. esculentum* was involved. The tetraploid was cross-sterile with the parent type.

A variation with less than the normal number of chromosomes has also been observed. Lindstrom has described a haploid tomato (12 somatic chromosomes as well as 12 in the germ cells). It was found in the F_2 of a varietal cross of completely fertile varieties. The haploid was smaller than normal and almost completely sterile. Its pollen was apparently impotent and few seeds were borne when other pollen was applied to its flowers. There was no tendency to pairing of the chromosomes, but evidence of a tendency toward reduction or separation in the meiotic division. It appeared that any germ cell receiving less than 12 chromosomes aborted.

A few diploid cells were noted in roots, so the plant was carefully perpetuated by cuttings in the hope that doubling might occur in a cell destined to become a growing tip and thus give rise to an absolutely homozygous tomato. Not only diploid but tetraploid plants were finally obtained.

Lesley and Lesley (*28*) have obtained tomato plants bearing fragments of single chromosomes by crossing a double trisomic ($2n+1+1$ chromosomes) with a normal plant. Certain of the progenies of this cross variously contained $2n+1$, $2n+1+$a fragment or $2n+$a fragment. These fragments or incomplete supernumerary chromosomes represent a partial trisomic condition. Such plants resemble certain trisomics. It has been found that fragmentation occurs in those unpaired chromosomes that lag behind in the course of meiosis.

The results of chromosome injury or of "knocking out" factors from chromosomes by irradiation may well be considered at this point. Lindstrom (*32*) irradiated various portions of tomato plants with radium-bearing needles. Irradiation of growing tips induced the most variations in the progeny of the treated plants. The irradiated parent plants showed no sudden variation except what could be accounted for as a result of direct injury by the radium in cases of overdosage. The progeny of these plants, however, showed much sterility,

pollen abortion, and malformation, supposedly caused by chromosome damage.

From these progenies Lindstrom isolated six variations that bred true and were shown to be due in each case to a single recessive factor. Five of these never before had been observed in tomato, while *l* for yellow foliage was shown to be the same factor that had been known for many years (table 1).

MacArthur (*38*) accomplished somewhat similar results by irradiating seeds with X-rays. All plants and fruits from these seeds were normal, but their progeny showed 12.4 percent of mutants of diverse forms—all of them economically worthless. There were many lethals and semilethals among them, only about a dozen being capable of perpetuation in the homozygous condition. Most of the variations appeared as chlorophyll and leaf abnormalities, and the plants were very slow-growing. Most of the new characters susceptible of genetic study, as in Lindstrom's radium-induced variations, behaved as single recessive factors.

Pepper

The principal contributions to the knowledge of inheritance in the pepper have been made by Halsted (*17*), Webber (*50*), and Dale (*8, 9, 10*) in this country, Ikeno (*20, 21*) in Japan, Atkins and Sherrard (*2*) in England, and Deshpande (*11*) in India. These workers are in general agreement on the inheritance of a number of characters but disagree on others. In cases of disagreement it appears that the more recent workers are probably more nearly correct because they have generally used larger progenies and have studied the results in F_3 and backcross generations as well as in the F_1 and F_2 generations. In some of the earlier work the importance of environment in its effect on expression of specific characters was not fully appreciated and difficulties were encountered. In table 3 are presented data on the inheritance of 16 characters in pepper. Conflicting data are not presented, but only those believed to be most dependable as indicated by the respective experimental procedures.

All investigators of foliage and flower color agree on the dominance of purple *A* over nonpurple *a* and on the close linkage or identity of factors responsible for foliage and flower color. Deshpande (*11*), however, only recently pointed out the effect of a second factor for purple foliage, an intensifier, *B*, which is without effect when *A* is absent. Numerous workers agree that red color of the ripe fruit is dominant over yellow and that green color of the immature fruit is dominant over yellow. Each is due to a single factor. Again Deshpande (*11*) contributed new information when he showed the effect of *A* upon fruit color. Plants with purplish-red fruit crossed with pure yellow gave four color types in a typical dihybrid 9:3:3:1 ratio in the F_2, namely, purplish red, pure red, yellow overcast with purple, and pure yellow. He also pointed out a close association between fruit color and seed color. Red fruits bear reddish-yellow seeds, while yellow fruits bear light or pale yellowish seeds.

Dale (*8*) plotted size distribution curves of pod lengths of F_1 and F_2 progenies of Coral Gem × Anaheim Chili (short × long pod) and certain backcrosses. The curves were skewed when plotted against class intervals of equal arithmetical magnitude, but were normal when plotted

on a logarithmic basis. It was concluded that the several undetermined factors for pod length exerted proportionate rather than additive effects, and that there was no disturbing influence of dominance.

TABLE 3.—*Inheritance in the pepper* (*Capsicum annuum*)

Characters [1]	Genes	Behavior in F_1	Segregation in F_2	Investigators
Plant habit:				
Normal *v.* dwarf		Normal	3 normal to 1 dwarf	Dale (*10*).
Flower color:				
Violet *v.* white		Intermediate violet	3 violet to 1 white	Ikeno (*20*), Deshpande (*11*).
Foliage and stem color: [2]				
Purple *v.* nonpurple	*A a*	Intermediate purple	3 purple to 1 nonpurple	Deshpande (*11*).
Intense *v.* normal purple	*B b*	Intermediate purple (intensifier only).	Together with *A* gives 1:3:8:4, three grades purple, 1 nonpurple.	Do.
Fruit color: [3]				
Red *v.* yellow or orange	*R-r*	Red	3 red to 1 yellow or orange.	Several.
Green *v.* yellow (immature).		Green	3 green to 1 yellow	Webber (*50*), Deshpande (*11*).
Fruit shape:				
Blunt *v.* nonblunt apex	*D-d*	Intermediate	3 not blunt to 1 blunt	Deshpande (*11*).
Bulged *v.* nonbulged base.	*F-f*	Bulged	3 bulged to 1 nonbulged	Do.
Fruit position:				
Pendent *v.* erect	*P-p*	Mostly pendent	3 pendent to 1 erect	Deshpande (*11*), Kaiser (*24*).
Fruit calyx: [4]				
Nonclasping *v.* clasping	*E-e*	Nonclasping	3 nonclasping to 1 clasping.	Deshpande (*11*).
Fruit flavor:				
Pungent *v.* mild		Pungent	3 pungent to 1 mild	Webber (*50*).
Fruit size and shape:				
Large *v.* small		Intermediate	All grades.	Several.
Elongate *v.* globose		do	Many grades; 3 factors indicated.	Deshpande (*11*).
Pedicel length:				
Short *v.* long		Short	3 short to 1 long	Do.
Pubescent foliage:				
Pubescent *v.* glabrous		Intermediate	15 pubescent to 1 glabrous.	Ikeno (*20*).
Inflorescence:				
Nonumbel *v.* umbel		Nonumbel	3 nonumbel to 1 umbel	Do.

[1] Hybrid vigor pronounced in plant vigor, height, yield, increased earliness, and fruit diameter (Deshpande (*11*). Length of pedicel, petal, and fruit linked with plant color and fruit position; these in turn linked with fruit color. All these factors on 1 chromosome (Deshpande (*11*)).
[2] Purple of stems and foliage closely linked with flower color; *A* affects fruit color, giving typical dihybrid ratio 9:3:3:1 in F_2.
[3] Seed color closely linked with flesh color.
[4] Nonclasping calyx closely linked with bulged base; 3 percent cross-over.

Branching habit, leaf size, and fruit size were shown by Webber (*50*) and others to be controlled by several factors, as evidenced by the intermediate character of the F_1 and the occurrence of all gradations of habit or size in the F_2.

Kaiser (*24*) showed the hereditary position of the fruit (pendent *v.* erect) to be due to a response to geotropic stimulus rather than orientation with reference to the plant axis or branch. A single dominant factor is responsible for the pendent position.

Dale (*10*) studied a leaf variegation in the pepper, which he found to be inherited maternally. Ikeno (*21*) observed other variegated forms in which the variegation was transmitted by either male or female gamete. Selfing of these races yielded only variegated offspring. Crossing variegated with green resulted in dilution of the variegated character. Cytoplasmic transmission is thought to have

been involved in both these instances. Other workers dealing with other plants have reported many cases of apparently cytoplasmic inheritance, particularly in cases of leaf variegation.

With one exception, all reports on the chromosome number of pepper are in agreement. Kostow, according to Huskins and La-Cour (*19*), reported a haploid number of 6 for *Capsicum annuum*, but later workers have consistently reported 12. Huskins and La-Cour (*19*) studied a dozen varieties among three subspecies and found only normal figures of 12 chromosomes in the haploid and 24 in the diploid states. Dixit's (*12*) results agreed with these.

No such interesting observations of polyploidy have been made in pepper as in tomato. It can hardly be said that polyploidy does not occur in pepper, but a search of recent literature failed to reveal record of studies of polyploids or chromosomal aberrations in this plant. Cases will come to light as the cytologist turns more attention to it, no doubt, for the family Solanaceae is one of the most productive of these types of variation.

Eggplant

As mentioned above, the eggplant has been studied very little from the cytogenetic standpoint, and most of the work done has been by other than United States investigators.

Halsted, of New Jersey (*17*), Nolla (*39*), of Puerto Rico, studying at Cornell University, and Kakizaki, in Japan (*25*), have studied the inheritance of color.

Halsted found two pairs of genes for fruit color. Purple skin *v.* colorless skin is due to a single dominant gene, as is also green flesh *v.* white flesh. He obtained four color types– *PG* purple (purple skin, green flesh), *Pg* pink (purple skin, white flesh), *pG* green (colorless skin, green flesh), and *pg* white (colorless skin, white flesh). He also studied a variegated fruit color that he found to be recessive.

Nolla confirmed Halsted's studies on fruit color and extended his observations to leaf and stem color, corolla color, and a striping of the anther. He found purple color in vegetative and floral parts to be either very closely linked with fruit color and with each other or controlled by the same gene. Without exception fruits with purple skins were borne on plants with violet or purple corollas and purple-tinged foliage. Green-fruit forms were borne on pure green plants with white corollas. Violet or purple corolla *v.* white was due to a single dominant factor, as was striping *v.* nonstriping of the anther. Monohybrid ratios in close conformity to the theoretical were obtained in the F_2 for all these characters.

In his studies of hybrid vigor in eggplant, Kakizaki (*25*) determined the seed and fruit weights, stem diameters, and heights of some 30 intervarietal crosses. He also recorded the F_1 behavior with reference to branching habit, leaflet size, fruit shape, color, and occurrence of calyx spines.

In the F_1 generation branching, leaflet size, fruit shape, and calyx spines were intermediate between the parents. Purple skin was dominant over white.

The mean seed weight of 30 crosses was 18 percent heavier than that of the mother parents. These results were generally consistent in 3

successive years, and were compared with selfed maternal parent seeds grown in the respective years.

The F_1 plants showed a mean stem diameter and height increase of 6 percent over the mean of the parents, and 36 percent increase in yield. The F_1 progenies were 70 percent more productive than the lower yielding parent and 17 percent more than the higher yielding parent. The best two parents for crossing gave F_1 progenies 90 percent more productive than the standard. Other Japanese workers have also noted marked hybrid vigor in eggplant. This work led to the commercial production of hybrid seed mentioned above.

It does not follow, however, that all intervarietal crosses will prove to be subsequently productive in all respects. Rao Balaji (*43*) has noted a high degree of partial sterility in the F_1 plants of certain wide crosses of Indian varieties. The pollen was 90 to 95 percent abortive.

Yasuda (*53*) has induced the formation of fair-sized parthenocarpic eggplant fruits by pollinating the flowers with petunia pollen. Cytological study showed that the petunia pollen tubes never reached the micropyle of the eggplant ovule, indicating that the stimulus of pollination alone induced ovary development. Injections of an extract of petunia pollen into ovarian tissue of the eggplant produced a similar effect, but tomato pollen extract was less effective.

The haploid chromosome number of eggplant is 12, the diploid 24. A few cases of polyploidy have been observed, but thus far none has any economic value. Janaki Ammal (*22*) found a tetraploid in a field culture that was nearly barren. Among the progeny of this tetraploid, triploids (36 chromosomes), tetraploids (48), and aneuploids of 44 to 46 chromosomes were found. He concluded that the triploids arose from a diploid pollen grain. Selfing of one of the triploids yielded 14 seeds, which produced 13 living plants. Of these, 2 were tetraploids and 11 were near-tetraploids, the counts of which could not all be determined with certainty. All these plants with aberrant chromosome numbers were decidedly undesirable from an economic standpoint and were almost entirely sterile.

BREEDING AND IMPROVEMENT OF CUCURBITS

T. W. WHITAKER, Associate Geneticist,
I. C. JAGGER, Senior Pathologist,
Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

THE cucurbits—cucumbers, muskmelons, watermelons, pumpkins, and squash—belong to the family Cucurbitaceae. Botanically they form rather a homogeneous group. While they are extremely diverse in fruit and vine characteristics, their floral structures are in many respects very similar.

In general, the family is characterized by the flowering habit known as monoecious. A monoecious species or variety is one that bears its pistillate or female organs of reproduction and its staminate or male organs in separate flowers, both kinds of flowers occurring on the same plant. In the Cucurbitaceae the female and male flowers are easily distinguished, even before they open. The showy corolla, or petals, of the pistillate flower is attached to the end of an easily recognizable, small, undeveloped cucumber, squash, or melon as the case may be (fig. 1, *A*). The male flower is at the end of an ordinary flower stem, without any enlargement (fig. 1, *B*). The corolla surrounds the pistils or the stamens in the respective sexes.

Cucumber, squash, and pumpkin are normally strictly monoecious, but certain varieties of muskmelon and watermelon show a modification of this condition that is termed andromonoecious. An andromonoecious plant is one that bears bisexual or complete flowers, instead of strictly pistillate ones, in addition to purely staminate flowers.

Although at a cursory glance these bisexual, complete, or hermaphrodite flowers appear like ordinary pistillates, examination within the corolla will show the presence not only of the stigmas but of functional stamens as well. Such flowers can be self-fertilized by their own pollen, or by the pollen from a purely staminate flower or from another complete flower on the same plant.

Our knowledge of the genetics of the cucurbits is very meager and fragmentary. There are several reasons for this. Probably the most important one is economic. The plants are large, and the space required to produce the numbers demanded for statistical significance in genetic experiments is enormous. Recently, however, promising results from systematic breeding programs with melons, watermelons, and squash have enriched our knowledge of the fundamental genetic nature of these crops (*13*),[1] and this in turn should be useful in further breeding work.

---

BREEDING RESPONSES AND POLLINATION TECHNIQUE

Studies made by numerous investigators of the cultivated cucurbits show that the several species are alike in certain breeding responses and variations in reproductive behavior. These points may well be treated here, since they seem to apply to the several crops.

Haber (*8*), working with Des Moines squash, a trailing variety of *Cucurbita pepo* L.; Scott (*25*) with three bush types of *C. pepo* (White Bush Scallop, Giant Summer Crookneck, and Zucchini), and also (*23*) with muskmelon; Porter (*18*) with watermelon; Cummings and Jenkins (*3*), with Hubbard squash, a variety of *C. maxima* Duchesne; and other investigators have shown that loss of vigor does not necessarily follow as a result of inbreeding these plants. This is quite contrary to the usual situation with normally cross-bred plants. Scott and Porter have shown that inbred lines having greater, equal, and less vigor or size of fruit may all be isolated from a given individual and that no difficulty may be expected from self-sterility in such inbreds. The work of Rosa (*21*), of Scott (*25*), and of Porter (*18*)

indicates that hybrid vigor does not occur as a result of crossing inbreds—also contrary to what might be expected.

Rosa (*20*) has sought evidence of metaxenia in muskmelon and Hibbard (*9*) in squash, but no such phenomenon was observed in either case. Metaxenia here refers to an immediate effect of pollen upon the character of the fruit or gross seed characters.

The constancy of these results for a wide range of varieties among several species of the cucurbits is rather conclusive evidence against the loss of vigor from inbreeding or the occurrence of hybrid vigor or of metaxenia in any of the cucurbits discussed in this article.

Another characteristic common to cucumber, squash, muskmelon, and certain other cucurbits is the wide variation within varieties in the ratio of male and female flowers. This ratio is profoundly influenced in many varieties of cucumber by changes in season (length of day) and in nutrients (*5*, *29*); and in squash by season and load of developing fruits borne by the plant (*24*). Under certain unfavorable conditions some varieties may become almost monosexual (all pistillate or all staminate), so that the investigator has great trouble in obtaining the desired set of fruit and seed.

Whitaker (*32*) has published a brief review of the literature on this subject, together with data on the typical sex expression of 49 varieties of cucurbits in 8 species and 4 genera and on deviations from typical expression in each species. His data showed very wide fluctuations in the ratio of male to female flowers in the several varieties and species. He concluded that sex determination in these cucurbits appeared to conform to Correns' theory as applied to monoecious flowering plants. According to this theory the gene complex for maleness may be represented as *A* and that for femaleness as *B;* another gene or complex, which may be indicated as *Z*, determines the sequence of activation or expression of *A* and *B*. *A* and *B* in themselves are believed to be relatively stable, but *Z*, which represents

TWELVE ***years ago, powdery mildew suddenly appeared in destructive form on melons in the Imperial Valley, Calif., the leading muskmelon-producing section in the United States. It could not be controlled by fungicides, and plant breeders began a search for disease-resistant material. In 3 years of careful testing they discovered several resistant varieties among melons imported from India. They were poor melons, but by suitable crosses their resistance to mildew was bred into good American varieties, and in another 4 years the first of the hybrids was released to California growers. Four more years of selection gave Powdery Mildew Resistant Cantaloup No. 45, which has superior shipping qualities in addition to disease resistance. This was released to growers in 1936, and the mildew problem is now largely solved in this area.***

the factors controlling the expression of maleness and femaleness, may be responsible for a reaction to environment that results in stimulation or retardation of *A* or *B* within very wide limits.

The pollination technique developed by Porter (*18*), working with watermelons, illustrates the general method employed in making controlled pollinations with flowers of the cucurbits. Approximately 24 hours before the flowers open, pistillate and staminate flowers are selected and covered with small muslin bags (in the case of melons and cucumbers, 1-pound manila bags are satisfactory). As soon as possible after the flowers open, the staminate flower is removed and its pollen is applied to the stigma of the pistillate flower. After pollination, the pistillate flower is covered with a 1-pound manila bag, held firmly in place by string or a paper clip. The pollination data are written on a tag attached to the flower, or directly on the paper bag. Several days after pollination the bags are removed, the fruit is tagged, and its location is marked by a stake.

It has been found unnecessary to cover the staminate flowers with a bag before they open. By placing a string around the corolla the flower is prevented from opening, and insects cannot enter. This eliminates one step in the process and increases the number of flowers that can be pollinated in a given length of time. Hermaphrodite flowers that are to serve as the female parent in a cross must not only be bagged before they reach full bloom but emasculated before the anthers shed pollen, to prevent self-pollination. Since the anthers may discharge pollen 24 hours before the flowers open, emasculation should be done more than 24 hours before opening. Purely pistillate flowers that require no emasculation need not be bagged before pollination, but the corollas may be tied shut as described above.

CUCUMBERS

THE cucumber, *Cucumis sativus* L., is supposedly a native of India (*30*), although plant explorers have never been able to discover a wild prototype. Cucumbers have been cultivated since earliest antiquity. Reliable records indicate that they were used as food in ancient Egypt, and were a popular vegetable with the Greeks and Romans. They are very important staple vegetables among the Russians and many orientals. In the United States cucumbers are widely grown in home gardens, in local-market gardens, and on truck farms for shipping, but in spite of their wide distribution under cultivation, their commercial importance is not so great as that of some of the other cucurbit crops.

Varietal Improvement

Cucumbers are usually divided into two classes according to use—slicing varieties and pickling varieties. This distinction is maintained even though the slicing variety may be used for both purposes. The plants of slicing varieties produce a moderate number of medium-length thick fruits generally with white spines. The pickling varieties are characterized by the production of very numerous, small, black-spined fruits. The fruits of most pickling varieties are so small, while still immature, that they are not adapted to slicing.

In England, a special forcing type of slicing cucumber is grown in greenhouses. This type sets fruit without any pollination and the fruits attain great length—over 2 feet in some varieties. Unless pollination is insured, the fruits are seedless, straight, dark green, and generally spineless. American consumers, however, do not like the huge English type, and American greenhouse varieties are either of the White Spine slicing type mentioned above or of an intermediate hybrid type somewhat longer than White Spine and darker green. Most growers of greenhouse cucumbers in this country use especially adapted strains; many use their own selections.

With one exception, all of our extensively grown commercial varieties of cucumber are the results of breeding, selection, or introduction by private growers and seedsmen. Many of the names commonly listed today are very old and represent varieties introduced from Europe. The origin of very few varieties is a matter of record, even in the case of comparatively recent introductions. Confusion in names is perhaps more extreme in cucumber varieties than in many other crops because of the ill-defined nature and lack of stability of so many of the supposed varietal characteristics. Vine habit, bearing habit, fruit size, shape, and color are all subject to marked variation under different conditions of culture, making the identification of varieties difficult. In all cucurbits, natural cross-pollination within a species complicates the problem of maintaining the purity and uniformity of stocks and varieties, but mixtures are especially difficult to detect in cucumbers because many so-called varieties have few really distinguishing features. With the exception of special greenhouse types and novelties, there are probably not over 15 to 20 really distinct cucumber varieties grown in this country.

It is questionable whether many of the supposedly superior varieties introduced successively in the last 50 years represented improvements distinct enough to justify new variety names. Seedsmen and growers have long attempted to develop varieties that will produce fruits of good size, uniform cylindrical shape, and attractive dark-green color before they begin to show signs of full maturity. Color is especially important because paleness or a yellowish tinge suggests too advanced maturity. A uniform dark green is most desired, and of course the flesh must be tender, crisp, and free from objectionable flavor.

A more recent breeding objective, not yet realized, is to develop varieties with a wide range of adaptability and resistance to various adverse conditions that result in low yields and poorly shaped fruits.

Early Cluster, Early Frame, Early Russian, Long Green, and White Spine were listed by the earliest seed catalogs in the United States, and have been grown here for at least 125 years. The first three are small, early, prolific varieties typical of the black-spined type; the last two bear larger, less numerous white-spined fruits that are more like the present popular slicing varieties. The origin of none of them is known.

Improved Long Green is a very long (12 to 13 inches), black-spined, dark-green, slightly tapered, late variety selected from London Long Green by D. M. Ferry & Co. and introduced in 1872. Arlington White Spine, a selection from White Spine that appeared about 1880,

is still a leading strain of White Spine. It is about 8 to 9 inches long, 2½ inches in diameter, medium green, and has a tendency to turn pale green or white at the blossom end. Davis Perfect (1905) was originated by Eugene Davis, of Grand Rapids, Mich., from a cross between White Spine and Telegraph, an English forcing variety. Davis Perfect is about 10 inches long, 2½ inches in diameter, white-spined, smooth, dark green, and distinctly tapered at both ends. Fordhook Famous, introduced by W. Atlee Burpee & Co. in 1902, was originated by A. McInnis, a grower in Ontario, Canada, who selected it from a cross of White Spine and Noa Forcing, made about 1894. It is a typical White Spine type, showing but little of the Noa Forcing character. Early Fortune was selected from a field of Davis Perfect by George E. Starr in 1906 and introduced by the Jerome B. Rice Seed Co. This has been an important and popular White Spine type for many years on account of its desirable size (about 8½ by 2½ inches), attractive cylindrical shape with rounded ends, good retention of green color, and productivity. Other popular current varieties are Stays Green or Black Diamond, Klondike, and Longfellow. The origin of these is obscure.

Deltus, a popular forcing variety, was obtained from a cross between White Spine and Tailby Hybrid made in 1896, the progeny of which was later crossed with Long Green. Adelbert Titus, a grower near Rochester, N. Y., originated the variety. Another popular variety of the Rochester district is the Irondequoit, developed by J. H. Wirt & Sons from a cross of White Spine and Telegraph made in 1904. In 1929 the New York Agricultural Experiment Station at Geneva, N. Y., introduced a parthenocarpic (seedless) variety named Geneva. It was developed from a cross of Arlington White Spine × Rochford Market made in 1916. All three of these are intermediate between the White Spine and the English types.

It is evident that the old White Spine is involved in the parentage of nearly all the slicing varieties grown in this country, both field and greenhouse types. Except in cases of known hybridization with Black Spine or English forcing sorts, one might be justified in considering all our white-spined field types simply as strains of White Spine.

Of the pickling type, Boston Pickling (1865), Chicago Pickling (about 1880), National Pickling (1929), and Snow Pickling (1906) are by far the most important. The first two are selections from unknown varieties grown near the places of origin indicated by the names. Snow Pickling was introduced by J. C. Snow, of Rockford, Ill., in 1906. National Pickling was developed by George E. Starr, of the Michigan Agricultural Experiment Station (1929), to meet the specifications of the National Pickle Packers' Association, who cooperated with the station in the work. The pickle packers desired a variety producing a large number of small, black-spined, dark-green fruits, similar to Snow Pickling but more nearly cylindrical or blocky, having the same diameter well out to the ends instead of being slightly tapered. These specifications are of special interest to those who pack pickles in glass containers and desire the most attractive product possible.

Disease Resistance

Reference to the appendix at the end of the section on vegetables in this Yearbook will show that several investigators, both in the United States and abroad, are trying to develop good commercial varieties having resistance to one or more of several diseases, particularly mosaic, downy mildew, and bacterial wilt.

Mosaic is a serious problem wherever cucumbers are grown in the Central, Eastern, or Southern States, particularly in the areas devoted to pickling varieties. Losses of 15 to 30 percent of normal production may be expected annually, and in many isolated cases much heavier losses occur.

Downy mildew is generally distributed. It is especially severe in the South, where it is in effect the dominant limiting factor in cucumber production. The losses usually depend on how early the disease attacks the plants, for it occurs every year and terminates harvesting soon after it becomes established in a field. Thorough spraying two to three times weekly is often an inadequate although a very expensive attempt at control.

Bacterial wilt is a serious disease, in the Central and Eastern States in particular. Plant pathologists estimate general losses to be 10 to 20 percent of a normal crop, while often certain fields may be practically a total loss.

The Bureau of Plant Industry has obtained a number of stocks of oriental varieties of cucumbers, chiefly from China, Japan, and India, some of which contain distinctly disease-resistant individuals. Considerable tolerance to mosaic has been found in certain inbred lines, and in some a measure of resistance to mildew and to wilt. High-quality American susceptible varieties have been crossed with the low-quality resistant kinds and the hybrids back-crossed to the American parents. Inbreeding is also being continued in efforts to isolate lines that are pure (homozygous) for resistance to specific diseases.

Bailey and Burgess, at the Maine Agricultural Experiment Station, are engaged in breeding cucumbers resistant to scab. This disease causes very severe losses by spotting the fruits, making them unsalable, as well as by reducing yields. It is confined almost entirely to the northernmost States. Inbred lines of commercial varieties are subjected to artificial inoculation to determine resistance or susceptibility. A number of lines apparently homozygous for resistance have been isolated. Preliminary studies indicate that resistance is dominant and due to a small number of factors, possibly only one.

MUSKMELONS

It is generally believed that the muskmelon (*Cucumis melo* L.) is native to India (*30*). Although there are indications that it was in use about the beginning of the Christian Era, it is not believed to have been in cultivation in very ancient times.

From its center of origin in northwest India it spread to China and Japan but has not reached a high state of development in those lands. To the westward, in Iran (Persia), in Turkistan, and in other regions of Asia Minor and about the Mediterranean, it was developed to a very

high state of perfection. Columbus first brought the species to the New World, and the natives of the West Indies and the mainland of North America quickly adopted it. By 1535 it was grown by the Indians as far north as Montreal, Canada.

Although the muskmelon is grown in every State, most of the commercial production is concentrated in a few sections of southern California, Arizona, Colorado, Texas, Michigan, and Indiana and in the tri-State area of Maryland, Delaware, and New Jersey.

There is a large number of varieties of muskmelons under cultivation in the United States. Many of them closely resemble one another, and improved forms are gradually replacing the older varieties. Muskmelon varieties may be arbitrarily divided into two classes—(1) shipping or commercial melons and (2) local-market and home-garden melons. Most shipping varieties produce comparatively small fruits with a tough rind and firm flesh and are adapted for shipping in standardized packages to distant markets. Local-market melons generally have softer flesh and are often large.

The name "cantaloup" is quite generally used in the United States to designate the small, oval, netted shipping type of muskmelon. Much confusion over the term has resulted from the fact that in Europe it is applied to a different type of melon, a long-keeping sort with a hard, ridged or warty rind, practically unknown to American growers (*14*). The American usage is now so well established that we must accept the name cantaloup as defined above. Obviously all cantaloups are muskmelons, but many varieties and types of muskmelons are not cantaloups by this definition. The kinds that lie outside the definition are the winter types, as Persian, Casaba, and Honey Dew, the Honey Ball, and the large, ribbed sorts like Bender and Montreal.

Varietal Improvement and Breeding

The number of varieties of muskmelon that have been and are being grown in this country is so great that no attempt to review the early history and development of all of them can be made here. Only the leading present varieties and a few of their supposed progenitors can be discussed, together with a brief reference to certain kinds that were formerly important.

Prior to 1850 most of the few varieties of muskmelon then grown in this country were introduced from Europe. Efforts were begun prior to that time to improve the crop from the standpoint of adaptability, particularly to the northern part of the country. Increased earliness and productivity were of special interest, since most of the imported varieties then available were apparently from warmer regions or for greenhouse culture. Nutmeg and Pineapple appear to have been varieties similar to our present cantaloups, and apparently the famous Netted Gem—later called Rocky Ford—was derived from the latter. Pineapple was described by Burr (1865) as roundish to oval, without ribs or with ribs faint, size small, skin olive green with abundant net markings. Nutmeg was described as slightly larger, ribbed, and otherwise similar. Both were old well-known European types. Most sorts described at that time were large, heavily ribbed, and netted. Numerous melons of the winter Casaba

or Persian type were described, but there is no indication that they were important. Most of the supposed American varieties mentioned by Vilmorin in 1856 were indicated as being related to the "American" variety Pineapple.

One of the earliest instances of muskmelon improvement in this country was the origination of the Christiana melon. It was developed about 1835 by Josiah Lovett, of Beverly, Mass., and is supposed to have been a cross of the variety Green Malta and an unnamed early sort. Despite poor quality, it was popular because of its earliness and was commonly listed for over 75 years.

About 1875 keen interest in muskmelon improvement was shown by both seedsmen and growers for the market, but the latter were perhaps the more active in actual selection and hybridization. Little artificial pollination appears to have been done, but natural crossing in mixed plantings furnished these growers with an abundance of material for selection.

About 25 rather distinct varieties besides the winter melons are of commercial importance or considerable home-garden interest and are listed by the leading seedsmen of this country at present. About a third of these are over 50 years old and only a half dozen are less than 25 years old. This survival indicates that the old "practical breeders" achieved results not easy to surpass and that the introducers brought in varieties well adapted to cultural conditions and consumer tastes. In 1901 there were about 25 or 30 fairly distinct and important sorts commonly listed, and about half of these are still current.

The old Surprise, of unknown origin, was introduced in 1876 and is supposedly the parent of Bender Surprise, a large, prominently ribbed sort that is an important home and market melon of the Northern States today.

The Netted Gem, apparently a form of the very old Pineapple, was first listed by W. Atlee Burpee & Co. in 1881. Its notably successful adaptation to shipping and market needs stimulated a great deal of interest in obtaining different and still better varieties of the same general type. Varieties of this type, with different flesh colors, slightly different sizes and shapes, and adaptability to different regions, soon were developed in the commercial muskmelon areas.

In 1886, Acme or Baltimore was introduced by J. Bolgiano, of Baltimore, and Emerald Gem, by W. Atlee Burpee & Co. Anne Arundel, introduced by Griffith & Turner, of Baltimore, in 1894, was believed to have been selected from Acme. About 1905 another selection, apparently from the Acme-Anne Arundel line of development, was introduced under the name of Sweet Air by George Tait & Sons, of Norfolk, Va. This same variety had been sold in Maryland as Knight for some years. The two names are known to be synonymous and the variety is still widely grown in the Chesapeake Bay section.

In 1897 the Netted Gem was renamed Rocky Ford to advertise its merits as grown and shipped by a group in the Rocky Ford, Colo., district, whereupon it became more popular than ever. When it proved to be adapted to the Imperial Valley, that desert area having been placed under irrigation a few years later, a truly phenomenal development of the cantaloup industry began. Several years later, green-

fleshed selections with salmon-tinted cavity were made from Netted Gem or Rocky Ford and appeared as Salmon Tint and Pollock 10–25; and deeply salmon or orange-fleshed selections appeared as Perfecto (1919) and Superfecto (D. V. Burrell & Co., 1926). These improved varieties of the Netted Gem type are more nearly spherical, more heavily netted, and thicker fleshed than the parent variety, and the present vogue is for solid salmon-colored flesh. They also differ somewhat in adaptation to climate, culture, and handling methods.

Hale Best, introduced in 1924 by I. D. Hale, became the leading commercial or shipping variety. It was developed by selection from a mixed stock obtained from a Japanese gardener in the Imperial Valley. The vines are medium in size; fruits small, usually weighing 2 or 3 pounds each, oval to round, slightly ribbed, well covered with dense heavy netting; flesh thick, firm-textured, solid salmon in color. Hale Best is the earliest of the high-quality shipping melons. The variety was quite variable when introduced, but improved forms have been and are being developed. Hale Best No. 36 and Hale Best No. 112 are popular strains at present. Since the variety is susceptible to mildew, it is certain to be displaced, at least in the Imperial Valley, by the new mildew-resistant varieties.

Hale Best is similar to Perfecto but is usually a few days earlier. The fruit is somewhat larger and the flesh possibly firmer, and it tends to hold up in shipment longer than Perfecto. Superfecto and Perfected Perfecto (Garwood & Woodside, 1925) are improved strains of Perfecto.

It is rather striking to note how the old Acme type and its elongate, green-fleshed descendants have tended to dominate the field in the Middle Atlantic States while the Netted Gem and its nearly round, salmon-fleshed derivatives have moved West and dominated that area from the beginning of the industry. Two other types or lines of development, from Osage, are also of particular interest, since the varieties that have resulted from them compete more or less with the two types just mentioned.

The Osage was originated by Roland Morrill, an active muskmelon breeder of Benton Harbor, Mich. It is claimed that it was selected from a natural cross of Orange Christiana and "a small black melon obtained from a Swedish gardener on the Osage River in Missouri", about 1880. It was introduced by Vaughn's Seed Store in 1887. Some believe that Osage is a selection from Miller Cream, with which it is now synonymous, regardless of its possible origin. Miller Cream was developed by J. D. Miller, of Elmira, N. Y., from a supposed cross of Sills Hybrid and Casaba. About 1890 one of Morrill's associates discovered a single plant in a field of Osage that was believed to be a cross between Osage and Netted Gem. Selection from this plant ultimately produced the variety Hearts of Gold that was introduced about 1895 or 1900. Morrill is said to have sent seed of certain selections from this supposed Osage × Gem cross to Paul Rose for trial, and the latter selected and introduced the varieties Paul Rose (also called Petosky and Osage Gem) about 1898 and Hoodo about 1900. Both were very similar to Hearts of Gold. Hoodoo and Hearts of Gold now are considered synonymous. It is further reported that from Osage Gem D. M. Ferry & Co. selected a strain named

Defender, introducing it in 1901; and that Burrell Gem is a strain of Defender, introduced by the D. V. Burrell Seed Co. in 1904. Burrell Gem and Defender are now synonymous. In 1907 D. M. Ferry & Co. introduced Extra Early Osage, a distinctly earlier variety of the Osage type.

Most varieties that attained importance and later practically disappeared are of unknown origin, although a few are of interest as examples of early purposeful hybridization. Cosmopolitan, introduced in 1894, was from a cross between Green-fleshed Malta and an unnamed netted type. Christiana has been mentioned.

The probable interrelations of some of the important muskmelon varieties are given in figure 2.

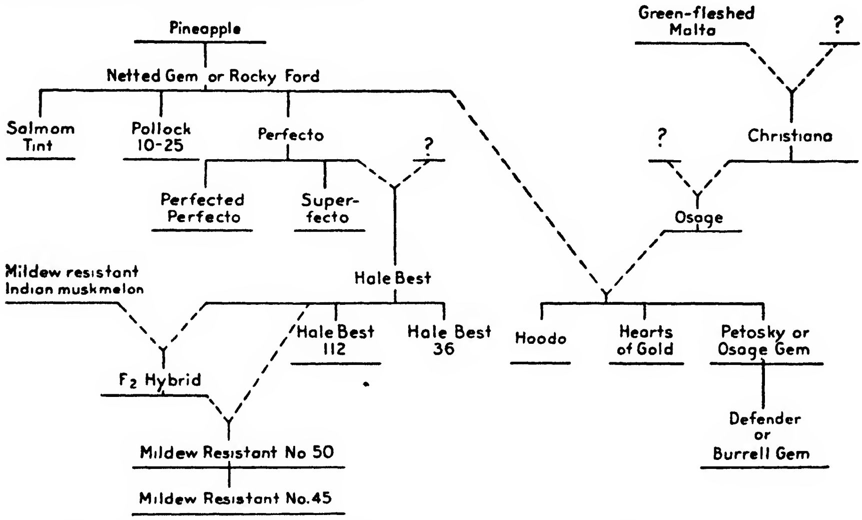

Figure 2.—Probable interrelations of some important muskmelon varieties.

Some old varieties still commonly listed are of unknown origin, but the date of introduction is known. These include Banana (1884), Texas Cannon Ball (1894), Hackensack (1883), Jenny Lind (1866), Montreal (1884), Tip Top (Livingston Seed Co., 1892), Eden Gem (1905).

Among more recent results of introduction and breeding should be mentioned Fordhook (Emerald Gem × Jenny Lind), introduced by W. Atlee Burpee & Co. in 1908. Honey Dew (the old French variety White Antibes Winter) was introduced into the United States about 1900. It not only became popular, but has also often been used as a parent in attempts to introduce its particular quality and flavor into varieties of the cantaloup type. Honey Ball is an important hybrid of Honey Dew and Texas Cannon Ball developed by W. H. Parker, a Texas grower. The original cross was made in 1916 and the variety introduced in 1924 by the Robert Nicholson Seed Co., of Dallas, Tex. Honey Rock is said to have been produced by crossing Champlain, Irondequoit, and Honey Dew. It was introduced about 1920 by Watt Richardson, of Ohio.

138904°—37——15

The origins of the Persian and the winter (Honey Dew and Casaba) types of melon are unknown. They are very old varieties and were introduced from Europe and Asia.

The Japanese melon is a distinct new variety that has become popular in the local markets of California. It is worthy of trial in other sections with a long growing season. The fruits are fairly large, round, flattened at the blossom end; the rind is tender, thin, pale grayish green with dark blotches, sparsely netted, and very slightly ribbed. The flesh is light salmon in color, soft, and juicy.

In the new variety, Weaver Special, the white rind of the Honey Ball is combined with the salmon flesh of the shipping-type cantaloup. It was selected from a cross by J. C. Fluke, of C. H. Weaver & Co., in the Imperial Valley, and introduced to the trade in 1933.

Figure 3.—J. T. Rosa (1895–1928), who made important contributions to the breeding of cucurbits, particularly muskmelons and watermelons.

Breeding for Disease Resistance

Thirty or more years ago growers noticed differential susceptibility of muskmelon to certain diseases. Hoodoo was mentioned as being resistant to blight.

In 1904 Blinn (*1*), of the Colorado Agricultural Experiment Station, started mass selection in the Rocky Ford variety in efforts to obtain strains resistant to rust (*Macrosporium cucumerinum* Ell. and Ev.). Beginning in 1906, progenies from individual plants and fruits were studied and subjected to selection under severe rust-infection conditions. Although selections were from open-pollinated individuals, marked success was obtained and strains of high commercial value were readily established. The andromonoecious habit of the variety resulted in less cross-pollination and mixture of strains than might be expected to occur in other varieties and species of curcurbits. Blinn also selected for superior shipping and eating quality and developed the first of the salmon tint strains of the Netted Gem type.

In 1925 powdery mildew (*Erysiphe cichoracearum* DC.) suddenly appeared in destructive form on melons in the Imperial Valley of California. Fungicides were found to be inadequate in controlling the trouble, and the crop was seriously injured for the next several seasons.

In searching for resistance, melon varieties and strains from all parts of the world were grown by J. T. Rosa (fig. 3), of the California Agricultural Experiment Station, and I. C. Jagger, of the United States Department of Agriculture, in the Imperial Valley in 1926, 1927, and 1928 (*12*). There was no appreciable success until 1928.

In that year numerous plants were found in several unfixed varieties from India that were practically free from mildew throughout the season, while other plants of the same varieties, and all plants of many other varieties, were badly injured. Unfortunately, the fruits of all the mildew-free plants were commercially useless because of poor shipping and eating qualities. Several commercial varieties were immediately crossed with the mildew-free plants. Resistance to mildew appeared to be inherited as a simple dominant Mendelian character. Back-crossing has considerably hastened the production of varieties that combine the resistance of the Indian melons with

Figure 4.—Comparative test of mildew-resistant and susceptible varieties of muskmelon in the Imperial Valley, Calif.: *A*, Powdery Mildew Resistant Cantaloup No. 45 is practically mildew-free; *B*, Hale Best has leaves largely destroyed by the disease.

the shipping and eating qualities of the American varieties. The development of resistant strains has now largely solved the mildew problem in this area.

Powdery Mildew Resistant Cantaloup No. 50, distributed for commercial trial in 1932, was the first fully resistant variety developed. The fruits are quite variable in size, shape, and quality. It was produced from a cross between the Hale Best variety and one of the resistant plants in the Indian varieties. Individuals from the F_2, or second hybrid generation, were backcrossed to Hale Best, and this was followed by two additional generations of selection. Starting with No. 50, four more generations of selection finally gave Powdery Mildew Resistant Cantaloup No. 45 (fig. 4), grown commercially for the first time in 1936. No. 45 is quite uniform in size, shape, and quality (fig. 5). It resembles Hale Best, but matures somewhat later. The flesh

has even a firmer texture than that of Hale Best. This characteristic gives promise of making it a superior shipping melon in districts adapted to its production

Powdery mildew-resistant strains of Honey Dew and Honey Ball are being developed for the Imperial Valley under the same project and

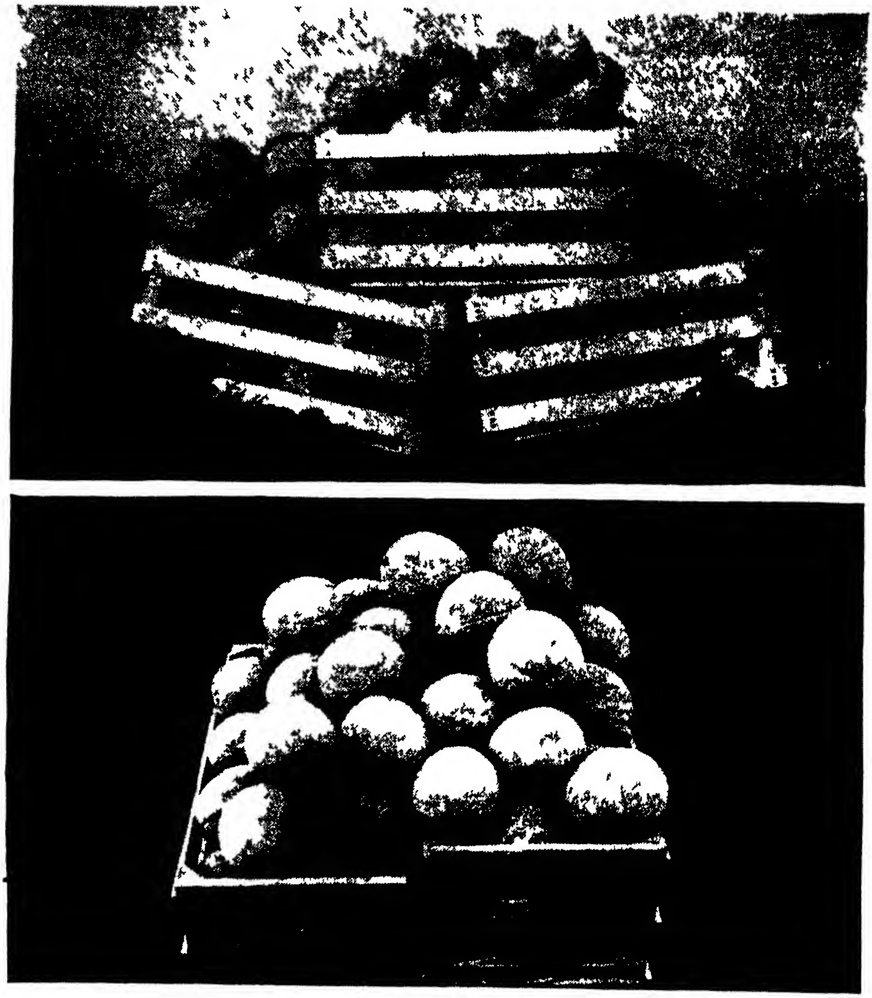

Figure 5.—Powdery Mildew Resistant Cantaloup No 45, showing type and uniformity of field run melons.

by similar means Powdery Mildew Resistant Honey Dew No 60 has been in commercial use in this district since 1935. Outside of freedom from mildew, it has not been quite so satisfactory from a commercial viewpoint as the standard Honey Dew. Backcrossing with Honey Dew and further selection should correct its objectionable characters

WATERMELONS

The watermelon, *Citrullus vulgaris* Schrad., is supposed to have been in cultivation some thousands of years, because it had a name in ancient Sanskrit. It is believed to be native to tropical Africa. In 1857, David Livingstone reported it as growing profusely in the Kalahari Desert after an unusually heavy rainfall. Both edible sweet and inedible bitter forms were present. The natives prized the sweet ones highly and made long journeys to obtain them. In parts of Africa the watermelon is a very important crop, furnishing not only food but also drink during periods of drought. In parts of the Union of Soviet Socialist Republics the fruits are important as a staple commodity, being pickled, used as a source of sirup, and eaten fresh. In parts of China certain firm-fleshed varieties are cut into strips, dried, and then made into pickles, sirup, preserves, or glacé sweets. The commercial production and shipping of watermelons to distant markets, to be used fresh, is much more extensive in the United States than anywhere else in the world. Although the crop is grown for home use and local markets in nearly every State, its culture for shipping is confined to the Southern States and to California.

In this discussion the word "type" is occasionally used in referring to groups of varieties of watermelons. It is admitted that the term is loosely used, for there is no single basis for classifying American watermelon varieties that is generally accepted as being adequate. They might be classified according to general features of shape and color, but that would bear no relation to use or to other qualities. A classification according to use, whether for home and local use or for shipping, would denote something concerning eating quality and rind characters, since the favorite varieties of any crop for home and local use are those that are highest in eating quality but are often too perishable for long-distance shipment. Within these two large classes, however, would be found nearly the whole range of colors and shapes. Any attempt to identify a few distinct types, all of which possess numerous qualities in common, presents perplexing difficulties. The problem is to establish a basis of classification in which the individual types are neither too exclusive nor too inclusive to be of practical value.

Varietal Improvement

A hundred years ago varieties of watermelon were ill-defined and seedsmen's listings usually referred to types rather than to varieties in the modern sense. With the exception of Bradford, which is still listed by a few dealers, no variety mentioned previous to 1850 is listed today, but a few were still common in the early 1900's. Among these were Black Spanish, imported from Portugal in 1827; Carolina, known in 1825; Imperial, Mountain Sprout, Seminole, and Mountain Sweet, introduced by southern growers around 1840 to 1850, or before. Bradford, Clarendon, Odell, Ravenscroft, and Souter all originated in South Carolina sometime prior to 1850.

Although the leading shipping varieties of today are comparatively recent developments, three home and local-market melons still listed by dealers are 60 to 75 years old. Peerless or Ice Cream was introduced in 1860, Phinney Early in 1870, and Georgia Rattlesnake about 1870 by M. W. Johnson, of Atlanta, Ga.

As in many other vegetable crops, the period from 1880 to 1900 marked the beginning of active varietal development and introduction by growers. A large proportion of the varieties listed at present were introduced during that time, and many of them are unsurpassed by later developments except in carrying better quality and disease resistance. The originators or introducers of only a few are now known, and the parentage of even fewer.

W. Atlee Burpee & Co. introduced Cuban Queen in 1881. Round Light Icing appeared in 1885. Kolb Gem, originated by Reuben F. Kolb, of Alabama, was introduced in 1885 by D. M. Ferry & Co. Hungarian Honey apparently was introduced from Hungary about 1885 by persons now unknown. Florida Favorite, said to be a cross between Pierson and Georgia Rattlesnake, was introduced by Girardeau, of Monticello, Fla., in 1887. Dark Icing was brought out by D. M. Ferry & Co. in 1888. Gray Monarch or Long Light Icing appeared in 1889.

Dixie was produced by George Collins, a North Carolina grower, and introduced by Johnson & Stokes in 1890. Stories differ as to whether Cuban Queen or the old Mountain Sweet was one of the parents, but they agree that Kolb Gem was the other. Cole Early was introduced by Cole's Seed Store, Pella, Iowa, in 1892. Sweetheart was developed by a Mr. Wittenmeyer of southern Indiana about 1890 and introduced by D. M. Ferry & Co. in 1894. One of the superior varieties, in eating quality, is Kleckley Sweet, developed by W. A. Kleckley, an Alabama watermelon grower. Its popularity and quality encouraged renaming, and Monte Cristo is one synonym that has persisted. It is said to be from a cross of Boss and Arkansas Traveler (introduced 1892). W. Atlee Burpee & Co. introduced the variety in 1897.

The Chilean, a variety, or perhaps more accurately a type, introduced from the west coast of South America, was first grown in California about 1900. Both white-seeded and black-seeded strains of this variety are now available and are extensively grown in the West. Angeleno was introduced to the trade by Johnson & Musser, of Los Angeles, in 1908, although it had been grown locally for some time. Its origin is obscure, but it is believed to have been selected from a South American stock related to Chilean. White-seeded and black-seeded strains are available, and they possess unusually dark red interior color and high quality. Another variety that gained prominence in the West is Klondike. Its origin is unknown, but it appeared about 1900. Solid-green and striped strains are grown. These three varieties are dominant in California at present and are hardly known elsewhere. Conversely, the important varieties elsewhere are largely unknown in the Pacific coast and southwest areas.

D. H. Gilbert, of Monticello, Fla., introduced Excel in 1906. The origin of Excel is not clear, but it was evidently a poorly fixed intervarietal hybrid. The introducer has stated that the original stock persisted in showing off-shape melons and variations in seed color. A white-seeded strain, introduced in 1926, was said to be free from these objections.

Tom Watson, the dominant shipping melon for the last 20 years or more, originated in Georgia and was introduced in 1906 by the

Alexander Seed Co., Augusta, Ga. It is a large, long, dark-green melon, with a thick, tough rind, that ships well. Unfortunately, however, the quality is only medium.

The original Irish Gray is reported to have been a volunteer plant found growing in an unoccupied stock-feeding pen by Charles Renew, of Rebecca, Ga., in 1913. Some believe the chance seed from which the variety was increased was brought in with feed imported from South America, but there is no proof of such an origin. In 1917 it was being shipped in carload lots, and it was doubtless second in importance in the early 1920's. It has yielded place, however, to Thurmond Gray, a variety originated and introduced by a Mr. Thurmond, a watermelon grower of Perry, Ga. Thurmond Gray first became prominent in 1923.

Stone Mountain originated in Georgia, near Stone Mountain, and was introduced in 1924 by the H. G. Hastings Co., of Atlanta. This melon is round or nearly so, green, of good quality, and a fair shipper. The vines are said to be prolific and resistant to foliage diseases.

The California Agricultural Experiment Station has effected some substantial improvements in uniformity, flesh color, eating quality, and shape of several varieties through the careful selection of lines inbred for several generations. California Klondike (from Klondike) was introduced in 1933, striped Klondike (from stock of the same name) in 1936, and Long Mountain (from Stone Mountain) in 1936.

In 1932 the Minnesota station introduced an unusually early variety, Northern Sweet, that extended the culture of the watermelon farther north. It was developed by inbreeding and selection from a stock introduced from the Union of Soviet Socialist Republics.

The Oscar H. Will Seed Co., of Bismarck, N. Dak., has introduced two varieties designed for growing in the northern Great Plains—Will Sugar in 1889 and Golden Anniversary in 1934. The latter is from a cross of Wikara × Kleckley Sweet, and the other from an unrecorded cross.

Breeding for Wilt Resistance

Until comparatively recently watermelons have been given very little attention by scientific workers. The work of Orton (*17*) is of more than ordinary historical interest, since it is one of the first recorded attempts of a plant breeder to synthesize a commercial variety resistant to a particular disease. Orton crossed the nonedible wilt-resistant citron melon with the edible wilt-susceptible watermelon variety Eden. From a large second-generation hybrid population, selections were made of plants with potentially desirable characters. By further selection a wilt-resistant edible variety, Conqueror, was produced in 1911. This variety never became a popular commercial type on account of unsatisfactory market and eating qualities.

Fusarium wilt is perhaps the most serious watermelon disease today, preventing profitable culture of susceptible varieties in many localities.

Wilt-resistant strains of commercial importance have been developed by Porter and Melhus (*19*) at the Iowa station, by selection from crosses of Orton's wilt-resistant variety Conqueror and certain commercial varieties. The two varieties developed by crossing (Iowa Belle and Iowa King) were about 65 percent resistant compared to the

1-percent-resistant commercial varieties. The exact origin of these two varieties is rather uncertain, but they were selected from apparently chance hybrids between Conqueror and one of the commercial varieties. Porter and Melhus also developed Pride of Muscatine, about 50 percent resistant, by selection of an inbred line of Kleckley Sweet. These three varieties were introduced in 1930.

The Florida station released a new wilt-resistant watermelon in 1936, the Leesburg, developed by M. N. Walker by pure-line selection in Kleckley Sweet grown on heavily infested soil.

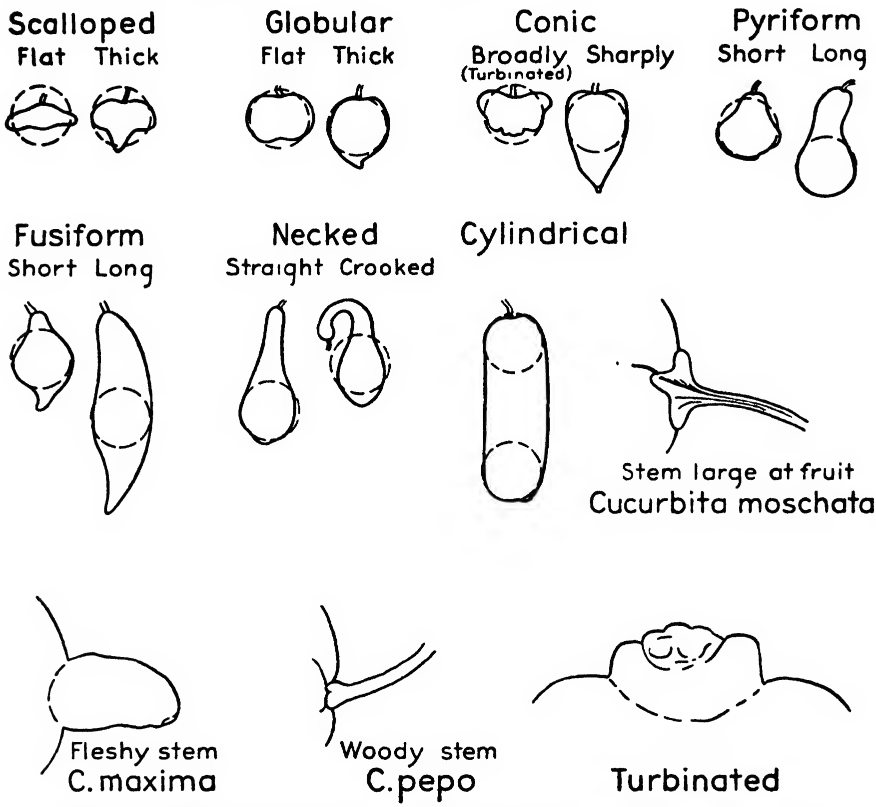

Figure 6.—Fruit shapes of varieties and stem characters of *Cucurbita* species.

The California station in 1936 introduced Resistant Klondike No. 7, a wilt-resistant sort selected from a cross of Iowa Belle × Klondike.

PUMPKINS AND SQUASHES

Pumpkins and squashes (*Cucurbita pepo* L., *C. moschata* Duchesne, and *C. maxima* Duchesne) are undoubtedly of American origin. Erwin (*6*) states that he has been able to identify fragments of stems, seeds, and fruits of *C. pepo* and *C. moschata* recovered from the cliff dweller ruins of the southwestern United States. With the help of archeologists, Erwin has determined that some of the material is from the basket makers, whose civilization antedates that of the

cliff dwellers; indeed, they were probably the oldest agricultural people of whom we have any record on the North American continent. Vavilov (*30*) believes that *C. moschata* originated in the Mexican-Central American region and that *C. maxima* originated in the Peruvian-Colombian-Ecuadorean area.

Pumpkin and squash varieties are numerous, but many are of local importance only. The fruits of the summer squash are used in an immature stage, while the rind is still tender. There are three important types—scallop, crookneck, and marrow or Italian. Each is represented by a number of varieties. Winter squashes and pumpkins are used when fully mature, after the rind has hardened. Hubbard is the leading type of winter squash, and Connecticut Field and Small Sugar are the leading pumpkins.

As has been previously stated, the differentiation of pumpkins from squashes is very uncertain, because as popularly classified there are both pumpkins and squashes in all three cultivated species of *Cucurbita*. Castetter and Erwin (*2*) have proposed that all varieties belonging to *C. pepo* and *C. moschata* be classified as pumpkins and the varieties of *C. maxima* as squash. Adoption of this classification would mean including the summer squash with the pumpkins, and various other changes in present popular usage. To seed growers and plant breeders the species are important, since varieties of the same species cross very readily, while those belonging to different species practically never cross in nature, contrary to popular belief. Figure 6 illustrates some of the principal differences among these three species of *Cucurbita*, and figure 7 illustrates stem characteristics.

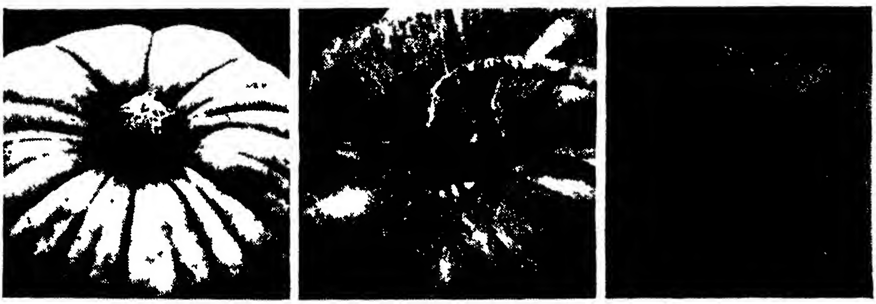

Figure 7.—Stem characters typical of the three species of pumpkin and squash. *A*, *Cucurbita pepo*; note five-angled stem not expanded next to fruit. *B*, *Cucurbita moschata*; stem neither angled nor fleshy but much expanded at attachment to fruit. *C*, *Cucurbita maxima*; stem neither angled nor expanded but fleshy and enlarged, becoming rather spongy when mature.

Varietal Improvement

A study of the origin of our present varieties of pumpkin and squash would require delving into colonial history, and in a number of cases the trail of a variety appears to lead into the history of Indian tribes, where it can no longer be followed.

Large Cheese and Connecticut Field pumpkins were common under those names before the Revolutionary War. Small Sugar is doubtless a hundred years old. The Cushaw has been listed in catalogs for

nearly a hundred years and represents a distinct form, perhaps a variety, that was being grown by the Indians in 1586.

Of the winter squashes, Acorn, a Turban form, was listed over a hundred years ago. Boston Marrow was described by Burr in 1865 as synonymous with Autumnal Marrow. This variety has been widely grown under one of these names in the United States and Europe for a hundred years. John M. Ives, of Salem, Mass., discovered its merits in 1831 and popularized it. He obtained the seed from a friend in Buffalo, N. Y., who in turn is said to have obtained it from a tribe of Indians (unnamed) that visited Buffalo periodically. The Hubbard was introduced to the trade by J. J. H. Gregory, a seedsman of Marblehead, Mass., about 1855. He stated that it had been introduced in the vicinity of Marblehead some 60 years before. The variety is thus conservatively 150 years old and probably older. Marblehead, also introduced by Gregory, is thought to have been imported direct from the West Indies about 1865. Winter Crookneck was described accurately, though not under that name, in 1686 and has been listed in seed catalogs for about a century.

The summer squash varieties are also very old. Both White Bush Scallop and Yellow Bush Scallop were common in 1865, and Burr says the yellow variety had been common for over a hundred years at that time. They were being shipped from the South to northern markets before the Civil War. Yellow Summer Crookneck and various forms of Vegetable Marrow [2] like some grown today have been listed in catalogs for over a century and are believed to have been in common use much longer than that. Three additional varieties—Italian Vegetable Marrow (before 1850), Cocozelle (Vilmorin, 1856), and Mammoth (1826)—were listed by seedsmen and described at the dates indicated; but some or all of them are certainly older, if we may judge by their importance and widespread distribution as stated or implied in the early references. A few variety names of 75 to 100 years ago have almost entirely disappeared from our catalogs and modern literature, but very few, among them Sweet Potato, common about 1850; Valparaiso (1827); and Yokohama, introduced from Japan about 1850.

Is there anything new in squash or pumpkin? Few distinct varieties have been introduced in the last 50 years that are superior, or even equal, to the important old-timers mentioned. Pikes Peak, a winter squash said to have originated in Iowa, was introduced in 1888. Fordhook was introduced by W. Atlee Burpee & Co. in 1889. Des Moines or Table Queen is said to have been introduced from his native country by a Danish farmer about 1900. It was 15 to 20 years later that it became popular and acquired its present name. Delicious, probably a selection from Hubbard, was introduced by Gregory in 1905. Golden Hubbard was introduced in 1896 by a Mr. Harrison of Painesville, Ohio. It was found as a chance plant in a field of Hubbard.

Because of their adaptability to pollination by insects, pumpkin and squash varieties and stocks are difficult to maintain free from mixture. This characteristic also is a prolific source of variation even within

[2] Vegetable Marrow designates a group of summer varieties of *C. pepo* or summer squash characterized by oval or elongate, cylindrical fruits that are harvested for use in a quite immature stage. Cocozelle and Zucchini are common varieties of Vegetable Marrow.

good stocks. In recent years numerous seedsmen have taken greater care in isolating selections made with specific objects in view. As a result, there are now available many good strains that represent improvements in uniformity, earliness, quality, and appearance overthe old parent stocks. The State experiment stations have proved the value of inbreeding in isolating superior, highly uniform strains, and their work indicates the practicability of selecting, from this g roup that has such rich potentialities, strains that will meet almost any set of specifications desired.

Twenty-five years ago Cummings and Stone (*4*), at the Vermont station, initiated their important studies of selection in open-pollinated and inbred lines of Hubbard squash with reference to yield, chemical composition, and quality. The Vermont Hubbard, an inbred line, was introduced in 1914, along with other slightly different strains. Some 6 years later the Vermont workers introduced Long Storage Hubbard, an inbred strain selected specifically for superior storage qualities. About 1921 Bushnell and others of the Minnesota station introduced Kitchenette, an earlier, smaller type of Hubbard produced by inbreeding and selection. In 1932 Krantz and others at Minnesota introduced a very large inbred selection from Hubbard under the name of New Brighton.

In 1932 Yeager and Latzke (*34*), of the North Dakota station, published an account of the development of their new Buttercup squash. This variety is of particular interest because it resulted from a breeding program designed to develop a highly productive, high-quality, highly nutritious squash, adapted to northern Great Plains conditions, as a substitute for the sweetpotato—meaning the real sweetpotato, not the Sweet Potato variety of squash. Inbred selections from a chance cross of Quality×Essex Hybrid best met these specifications. Buttercup is a small (3 to 3½ pounds), yellow, neat, Turban-like variety with flesh of an unusually high solids content (25 percent and higher), containing about 15 percent of starch, 5 percent of sugar, and 2.5 to 3.0 percent of protein. It came from a wide cross and has been difficult to make uniform.

Other varietal improvements have been made to meet specific market demands. In 1936 the California station introduced Gray Zucchini, an inbred strain of Zucchini, and the Connecticut station introduced Connecticut Straight Neck from a Straight Neck inbred× Golden Summer Crookneck.

INHERITANCE IN THE CUCURBITS[3]

CYTOLOGICALLY this family has proved to be less interesting than the vast amount of variation within the group would indicate. Furthermore, the material does not lend itself easily to cytological investigation by the ordinary methods. Although a long list of genera and species has been investigated, there are no established cases of polyploidy, fragmentation, or other gross chromosomal phenomena. Of the cucurbits, cucumbers (*Cucumis sativus*) have 7 pairs of chromosomes, muskmelons (*C. melo*) have 12 pairs, watermelons (*Citrullus vulgaris*) have 11 pairs, and the pumpkins and squashes (*Cucurbita pepo*, *C. moschata*, and *C. maxima*) have 20 pairs (*31*).

[3] This section is written primarily for students or others professionally interested in breeding or genetics.

Inheritance in Cucumber

Information regarding the hereditary behavior of specific characters in the cucumber is very meager. It has been shown that (1) spininess is dominant over spinelessness; (2) black spines are dominant over white ones; and (3) the tendency toward the production of fruit lacking viable seeds (parthenocarpic fruit) is apparently associated with black spines, suggesting that these factors are linked.

Some recent work by Hutchins (*10*) has uncovered an interesting green-flowered variation. This variant is female sterile. As a result, the characteristic can be carried along only in the heterozygous condition. Tests with the normal yellow-flowered form indicate that this green-flowered character is dependent on a single gene recessive to normal yellow, the second-generation hybrid population segregating into 3 normal yellow plants to 1 green-flowered plant.

Inheritance in Muskmelon

Since very early times melons have attracted both the professional and the amateur plant breeder. Sagaret (*22*) in 1824, some 40 years before the time of Mendel, made a series of interesting genetic studies with melons. He was undoubtedly one of the earliest forerunners of modern geneticists. His work very definitely shows that he had the idea of contrasting unit characters in his crosses. However, he failed to follow his results into the F_2 generation or to analyze them mathematically. From a cross of two distinctive varieties, Sagaret found that in the F_1 yellow skin was dominant over white skin, netted epidermis over smooth epidermis, pronounced ribbing over smooth ribbing, and acid flavor over sweet flavor.

Lumsden (*16*) attempted to determine the inheritance of the following contrasting fruit characters: Yellow versus green skin color, round versus obtuse-elliptical shape, large versus small seeds, ribbed versus nonribbed, netted versus smooth surface, and large versus small fruit size. He worked with commercial stocks of unknown purity, but they were apparently heterozygous for the characters studied, for he reported segregation into numerous gradations together with the appearance of both parental types in the F_1. No definite conclusions can be drawn from his work. His own conclusions concerning dominance of specific characters are not supported by his data. With the possible exception of skin color, it would appear that all the characters he observed were determined by multiple factors.

Rosa (*21*) has obtained ratios indicating monohybrid segregation of certain characters; that is, the monoecious condition was dominant over the andromonoecious condition; the tricarpellate ovary was dominant over the five-carpellate ovary. In some earlier work, Rosa (*20*) had been able to demonstrate that pollen from different sources has little if any immediate effect on the qualitative characters of the fruit.

As all varieties of muskmelons are notoriously cross-fertile, most of the commercial varieties are highly heterozygous. It is possible to isolate superior strains by selection and inbreeding. These methods have been adopted to stabilize varieties of commercial importance.

A carefully planned inbreeding program at the California station, continued in a few cases to the seventh generation with Salmon Tint, Hale Best, Honey Dew, Honey Ball, and Casaba varieties, has clearly demonstrated that no deleterious effects result from this amount of inbreeding.

Inheritance in Watermelon

Recently a comprehensive, systematic breeding program at the California station has produced much information that will be of value in dealing with problems of watermelon breeding in the future. Besides developing an effective pollination technique, Porter (*18*), has studied the biology of fruit setting in relation to certain environmental factors and has made observations on the effects of inbreeding.

With reference to inbreeding, strains were isolated that were comparatively homozygous for fruit-shape factors and for a number of fruit characteristics—for example, flesh color, texture of flesh, solidity of fruit, etc. Most varieties show no loss of vigor after four to five generations of inbreeding.

In the case of watermelon wilt, the phenomena of resistance and susceptibility are relative. The commercial varieties are as a rule very highly susceptible to wilt; the inedible varieties (as stock citron), on the other hand, are more or less resistant. No variety observed to date seems to be completely immune.

Rosa (*21*) found that the majority of watermelon varieties are monoecious and a few varieties are andromonoecious. Crosses of varieties representing these two types indicated that the difference was monogenic, the monoecious condition being dominant.

Porter and Poole, at the California station, have determined the mode of inheritance of a number of characters in the watermelon. All of the characters investigated gave monohybrid ratios, and there was no evidence of linkage among any of them. Their experiments indicate that (1) in flesh color, red is dominant over yellow; (2) in seed-coat color, black is dominant over white and tan; (3) in fruit-skin color, dark green is dominant over striped and white; (4) in rind, toughness is dominant over tenderness; and (5) in fruit shape, short is dominant over long.

Inheritance in Pumpkin and Squash

The question of whether pumpkins and squashes will cross has always interested amateur gardeners. Considerable confusion has arisen from an imperfect understanding of botanical relationships. There is no accepted basis for distinguishing pumpkins from squashes. Botanically they belong to three species of the genus *Cucurbita*. As popularly classified there are both pumpkins and squashes in all three species.

Castetter and Erwin (*2*) and Erwin and Haber (*7*) have shown that varieties belonging to the same species cross very readily, while those belonging to different species practically never cross in nature. However, cross-pollinating certain varieties belonging to *Cucurbita pepo* with varieties of *C. moschata* has produced partially fertile hybrids. Until recently only sterile hybrids, or complete failure to develop fruits, had resulted from cross-pollinating varieties of *C. maxima* with varieties of *C. pepo* and *C. moschata*. Van Eseltine, at the New York

(State) station, has recently obtained fertile hybrids of reciprocal crosses of *C. pepo* and *C. moschata* and of *C. maxima* and *C. moschata.* Dana, of the Bureau of Plant Industry, in working for curly top resistance in squash varieties, obtained hybrids of *C. moschata* and *C. maxima* that were self-fertile in the F_1 but male-sterile in the F_2. He has backcrossed the hybrid to both parents and obtained fertile backcross progenies.

Early attempts at a genetic analysis of this genus have proved to be practically worthless, chiefly because the investigators were using heterozygous material in their experiments. They underestimated the value of establishing pure lines as a primary factor in securing reliable results in genetic experiments.

The first attempt at a careful genetical analysis of *Cucurbita* was made by Sinnott and Durham (*26*). They used several varieties of *C. pepo.* After being inbred for several generations, the original types were evidently homozygous, as evidenced by their behavior. At this point, using the inbred material, an investigation of the inheritance of certain characters was initiated. From their results the several characters studied appear to be inherited, as indicated in table 1.

TABLE 1.—*Inheritance in summer squash fruits, Cucurbita pepo (after Sinnott and Durham)*

Contrasting characters	Behavior in F_1	Segregation in F_2
Exterior "ground" color.		
White *v.* yellow	White	3 white to 1 yellow (certain crosses produce 15:1).
Yellow *v.* green	Yellow	3 yellow to 1 green.
White *v.* green	White	12 white to 3 yellow to 1 green
Exterior striping:		
White fruits, nonstriped *v.* green-striped.	do	43 white and 9 green-striped.
Yellow fruits nonstriped *v.* white-striped.	White-striped	Complex.
Flesh color:		
White *v.* cream	White	3 white to 1 cream.
Surface:		
Smooth *v.* medium warty	Warty	3 warty to 1 smooth
Smooth *v.* very warty	do	15 warty to 1 smooth
Shape:		
Disk *v.* sphere	Disk	9 disk to 6 sphere to 1 long. Different crosses gave different results. Maybe 1, 2, or more factors involved. In some, the situation is very complex

Sinnott and his coworkers (*27, 28*) have greatly extended this analysis, particularly with regard to the genes governing sizes and shapes in fruits. In general, these characters appear to be determined by numerous factors, so their inheritance is complex and not completely clear. It has been shown that in the cucurbits inbreeding up to at least 7 to 10 generations does not result in a general decline in the vigor of the plants. This behavior is in distinct contrast to that of corn, onions, etc., where inbreeding immediately brings about a decline in vigor.

Hutchins (*11*), at the Minnesota station, has shown in different color types of Hubbard squash (*Cucurbita maxima*) that green is partially dominant to blue. The F_1 was intermediate in color, and the F_2 and backcross populations segregated as for a single factor. Lotsy (*15*) showed that in *C. maxima* exterior fruit-color inheritance

is for the most part complex. In a cross of Turban (a red strain) × Green Hubbard, the F_2 segregated into 3 reddish to 1 green. The dominance of the red was incomplete. In a cross of Turban × Silver Gray, a very wide assortment of colors occurred in the F_2. Lotsy also showed that the Turban character (fig. 2), caused by incomplete enclosure of ovarian tissue by receptacle or torus tissue, is due to two dominant genes. Turban × Green Hubbard gave an F_2 segregation of 15 Turban forms to 1 non-Turban form.

ONION IMPROVEMENT

H. A. JONES, Principal Olericulturist,
Division of Fruit and Vegetable Crops
and Diseases, Bureau of Plant Industry

THE onion is used as a food and for seasoning in nearly all countries, and its culture no doubt dates back to very remote antiquity. According to Sturtevant, as reported by Hedrick (*9*),[1] it is—

One of the things for which the Israelites longed in the wilderness and complained about to Moses. * * * Onions were prohibited to the Egyptian priests, who abstained from most kinds of pulse, but they were not excluded from the altars of the gods. * * * They were introduced at private as well as public festivals and brought to the table. The onions of Egypt were mild and of an excellent flavor and were eaten raw as well as cooked by persons of all classes.

ORIGIN, CULTURE, AND USES

BAILEY (*2*) describes eight species of onions cultivated in North America. *Allium neopolitanum* Cyr. and *A. moly* L. are grown as ornamentals. Garlic (*A. sativum* L.) is used mainly for seasoning. The leek (*A. porrum* L.), the Welsh or Japanese onion (*A. fistulosum* L.), and the shallot (*A. ascalonicum* L.) are all used in the green condition. The tops of chives (*A. schoenoprasum* L.) are used for seasoning. *A. cepa* L. is the species cultivated most extensively. Bailey divides this species into several botanical varieties as follows: (1) The extensively cultivated bulbing type of onion propagated by seed; (2) the potato or multiplier onion, which propagates by branching at the base; and (3) the top onion, which forms bulbils in the inflorescence, which are often used for propagation.

Vavilov (*21*) names the middle-Asiatic center, comprising northwestern India, all of Afghanistan, the Soviet Republics of Tajik and Uzbek, and western Tien Shan, as the primary place of origin of the commonly cultivated onion, *Allium cepa*. As secondary centers of origin of this species he lists (1) the Near East, which includes inner Asia Minor, the whole of Transcaucasia, Persia (Iran), and the alpine Turkmen Republic, and (2) the Mediterranean region. For the Japanese onion, *A. fistulosum*, which is cultivated extensively in the Orient, Vavilov gives the primary place of origin as the Chinese center, which comprises alpine central and western China and the adjacent lowlands.

From these centers of origin the onion has spread to all countries where the crop can be grown at some season of the year. Just when the cultivated onion was first introduced into North America is not known, but at present it is cultivated everywhere in this country as a

[1] Italic numbers in parentheses refer to Literature Cited, p. 249.

138904°—37——16

home-garden and market-garden crop. Extensive commercial production, however, is confined to special regions.

The early crop for shipment is grown chiefly in Texas, California, and Louisiana from transplanted plants set in the field in late fall and early winter and harvested the following April, May, and early June. The predominant variety is Yellow Bermuda, but Crystal White Wax and Creole are also grown to a considerable extent. These varieties are used for the early crop because they produce bulbs during the time of the year when the days are short. The Bermuda type cannot be stored successfully for more than a few weeks, but Creole is a good storage onion.

The intermediate crop is grown primarily in Texas, New Jersey, California, Oklahoma, Washington, and Iowa from transplanted seedlings and from dry sets, the crop being harvested chiefly during June and July. In Texas the principal intermediate variety is the Yellow Bermuda; in California, the Stockton Yellow Globe and California Early Red; in Iowa, the Yellow Bottleneck; in the East, the Ebenezer, Yellow Strasburg, and others of the same type. In Texas and California the intermediate crop is grown from transplants; in other districts dry sets are used.

The late or main crop, which is produced chiefly in Michigan, New York, Indiana, California, Ohio, Massachusetts, Colorado, Minnesota, Idaho, Oregon, Washington, Wisconsin, and Utah, is usually seeded directly in the field and harvested in August and September. This crop, most of which is stored, supplies the demand from September until late March or April. Storage varieties are not

OFTEN *an onion crop that might have been a profitable one brings the grower a loss because of unfavorable weather conditions and the occurrence of certain insect pests and diseases that take their toll in both field and storage. Smut occurs in practically all of the main onion-growing States of the North, while pink root is present in most of the onion districts of the South and West. Onion thrips are always present on both the bulb and seed crop. Smudge, neck rot, and other diseases take an additional share of the crop after harvest. Other losses occur because of premature seeding in the field and sprouting in storage. Until very recently, little has been done to alleviate these difficulties by scientific breeding methods. Present researches and experiments, however, make the possibility of preventing many such losses by developing superior varieties of onions more and more promising. In most cases resistant varieties and strains have been found, and in some cases promising hybrids have been produced and are under test.*

the same for all sections. In California, Australian Brown is used; in Oregon, the Oregon Danvers; in the Rocky Mountain States, Sweet Spanish and Mountain Danvers, and in the Northern States from Minnesota to Massachusetts, the yellow globe type such as Yellow Globe Danvers, Southport Yellow Globe, and Ohio Yellow Globe. Other varieties stored to some extent are Southport Red Globe, Southport White Globe, Red Wethersfield, White Portugal, Ebenezer, and Yellow Strasburg. With the exception of Sweet Spanish, these storage varieties are rather pungent.

During seasons of low production imports have been chiefly from Spain, Egypt, Chile, Italy, and Canada.

The quantity of onions consumed per capita in the United States is fairly constant regardless of price. During years of overproduction a portion of the crop is usually plowed under, and during years of underproduction imports are increased. The onion market is not very elastic, oversupplies are not readily absorbed, and consequently it is rather easy to have overproduction. As a rule, onions are used by most families in comparatively small quantities but fairly constantly throughout the year for seasoning, in salads, and as a main dish cooked in a variety of ways. Onion salt is also being manufactured in considerable quantities for use in catsup, chili sauce, soups, and sausage. But while the quantity of onions consumed per capita is not large, the total amount used gives this crop a commercially important place among the vegetables. The average onion acreage for the United States during the 5-year period 1928–32 was 84,430 acres, with a production of 13,247,000 100-pound sacks, giving a yearly return to the producers of approximately $17,353,000.

VARIETAL ADAPTATION

Among the onion varieties grown in the United States there are many types differing in size, shape, and color of bulbs, pungency, keeping quality, time of maturity, and tolerance to diseases, insects, sunscald, and high and low temperature. It has been necessary to maintain a considerable number of varieties, partly because of consumer demands relating to season and use, but chiefly because of the different environmental conditions under which the crop is grown. The storage onions of the North, for example, do poorly in the South, and the extra early varieties commonly grown in the South are ill-suited for production in the North.

The adaptability of varieties to certain regions, according to Magruder and Allard (*14*), is often determined by length of daylight, called the photoperiod. The time when bulbing is initiated is determined by the length of the photoperiod and not by the age of the plant, and the minimum photoperiod necessary to initiate bulbing varies with different varieties. The investigators named above were able to group the varieties into classes according to the minimum photoperiod required to produce 100 percent normal bulbs as follows: 12 hours, Yellow Bermuda, White Creole, and Early Grano; 13 hours, California Early Red, Yellow Strasburg, Ebenezer, and Yellow Danvers Flat; 13.5 hours, Early Yellow Globe, Mountain Danvers, Ohio Yellow Globe, Australian Brown, White Portugal, Southport Yellow Globe, and Sweet Spanish strain no. 1; 14 hours, Red Wethersfield,

Southport Red Globe, and Italian Red; 14.25 hours, Yellow Globe Danvers; normal day (maximum of 14.9 hours), Sweet Spanish strain no. 2. Most commercial varieties are not homozygous or pure for the genes that determine the minimum photoperiod for bulbing, so there may be some plants that bulb at a shorter photoperiod than is characteristic for the variety.

Early maturity, according to Magruder and Allard, seems to depend on the ability of the plant to start bulb formation at short photoperiods and to proceed very rapidly with the process after the minimum period for bulbing is reached. In the North it is almost impossible to secure good yields of the extra early varieties like the Bermudas, Early Grano, and Creole by sowing seed directly in the field, because seeding is usually done at a date when the length of day has already passed the minimum for bulbing. Consequently the plant develops only a few leaves and a small bulb. To secure large bulbs of the extra early varieties in the North it is necessary to sow seed early in a greenhouse or in a hotbed in order to have large plants before the minimal photoperiod for bulbing occurs.

The late-maturing varieties of onions usually do poorly in the South, chiefly because the photoperiod required for bulbing comes during hot weather, when sunscald, thrips, and pink root combine to retard the growth of the plant. Lateness of maturity, according to Magruder and Allard, may be due to a long photoperiod requirement, to a slow rate of bulb development after the minimum occurs, or to a combination of the two. Sweet Spanish, a late variety, is able to produce fair crops in the South because it is somewhat resistant to sunscald, thrips, and pink root.

In central California there is a considerable acreage of the so-called intermediate crop of onions. The seed is usually sown in field beds in late August and the seedlings are transplanted in late November and December. During the winter and early spring the plants usually make a large vegetative development. Bulbing does not begin in the spring until the hours of daylight reach the minimum for the varieties in question. For this crop, varieties such as Stockton Yellow Globe, California Early Red, and Italian Red are used. If the late varieties of the North or the early varieties of the South are used they make a good vegetative growth, but in the spring the plants form seed stems instead of bulbs.

These few points regarding adaptation are brought out to show why a variety may do well in one district and be worthless in another. Sweet Spanish is much more widely adapted than many varieties because of its resistance to high temperature conditions and to certain insects and diseases. Other varieties will be more widely adapted when plant breeders incorporate in them genes for resistance to diseases and insects and others that permit them to grow under a wider range of climatic conditions.

INTRODUCTION OF PRESENT COMMERCIAL VARIETIES

It is difficult to obtain authoritative information on the method and time of introduction of the older important commercial varieties. the first mention in seed catalogs of certain important varieties is as follows: Silverskin (White Portugal), 1810; Crystal Wax, 1901; Red Wethersfield, 1849; Ohio Yellow Globe, 1901; Southport Red

Globe, 1889; Southport White Globe, 1889; Southport Yellow Globe, 1888; Yellow Danvers (Flat), 1866; and Yellow Strasburg, 1844. According to Morse (*17*), the variety Australian Brown was introduced into North America from Australia in 1894, under the name of Brown Spanish, but later was renamed by W. Atlee Burpee. An improved strain, Australian Brown U. C. No. 1, was introduced by the California Agricultural Experiment Station in 1935. Sweet Spanish seed was secured by the United States Department of Agriculture from Luis Tono, American consul in Spain, in December 1908, under the name of Denia, and was distributed to seedsmen and several agricultural experiment stations. An improved strain, Sweet Spanish Colorado State No. 6, was introduced by the Colorado Agricultural Experiment Station in 1936. According to Morse (*17*), Prizetaker was first offered to the trade in America by William Henry Maule in 1888, from seed grown by C. C. Morse the preceding year at Santa Clara, Calif. In Europe this variety was known as Spanish King. The Early Grano onion, named and introduced by the New Mexico Agricultural Experiment Station (*8*), was secured from Spain in 1925 under the name of Valencia Grano by the Barteldes Seed Co., of Lawrence, Kans.

Morse (*17*) states that the California Early Red has been developed from the Red Italian Tripoli. The latter was probably brought to California by the early Italian emigrants before 1900. An improved strain, California Early Red, U. C. No. 1, was introduced by the California Agricultural Experiment Station in 1935. The variety Stockton Yellow Globe was originated by a number of American and Japanese growers in California in response to a demand for a nonbolting yellow globe onion; consequently there are a number of strains of this variety, the type of which has not as yet become definitely established. According to Erwin and Harter (*6*), the parent stock of Yellow Bottleneck was "Birn Zwiebel" and was secured from Germany in the late sixties by a Mr. Lafrenz, of Davenport, Iowa. The Creole variety was probably brought to Louisiana by the early French settlers. Yellow Bermuda (formerly called White Bermuda) was probably introduced from the Canary Islands some time prior to 1901.

VARIETAL IMPROVEMENT

OFTEN an onion crop that might have been a profitable one brings the grower a loss because of unfavorable weather conditions and the occurrence of certain insect pests and diseases that take their toll in both field and storage. Smut occurs in practically all of the main onion-growing States of the North, while pink root is present in most of the onion districts of the South and West. Onion thrips are always present on both the bulb and seed crop. Smudge, neck rot, and other diseases take an additional share of the crop after harvest. Besides these, other losses occur because of premature seeding in the field and sprouting in storage. Little has been done until very recently to alleviate these troubles by scientific breeding methods. Hope of preventing many losses in the future by developing varieties resistant to various insects and diseases and certain unfavorable climatic conditions seems more and more promising. Some of the work actually under way is described in later sections of this article.

Commercially Maintained Seed Stocks

To give a comprehensive idea of onion improvement as it is being conducted at present, it will be necessary to review methods employed by commercial interests as well as by State and Federal investigators. Most of the onion seed produced at the present time is grown in California. There the mother bulbs of the different varieties are grown like those for market, with the exception that the rate of planting is heavier so that the plants are more crowded and a somewhat smaller bulb is produced. These are grown by contract at so much per 100-pound bag. Harvesting is usually done in August and September, and the bulbs remain in the bag until time to plant in the field in late November or December. Before planting, most seedsmen pass the mother bulbs over a grading table to sort out the off-color ones and at the same time select mother bulbs of good type to plant for the production of stock seed. As a rule, the bulbs of the various varieties are distributed to ranchers who contract to grow the seed at so much per pound.

If mother bulbs are selected carefully, it is possible to maintain fairly uniform stocks of the different varieties. Onions, however, are highly cross-pollinated, and commercial varieties have a very mixed heredity. Usually there are enough differences between the plants of a variety so that it is possible to select rather widely for type. It is seldom that any two people have exactly the same idea of what the type should be in making selections. As a consequence there are many strains of each variety. Also, by following the selection method exclusively certain recessive colors and off-types are never bred out; they are carried along indefinitely. Progressive seedsmen, however, are beginning to use scientific methods to develop strains that are more uniform in size, shape, and color. Breeding for the development of resistance to diseases and insects, however, is being conducted chiefly by the Federal Government and by the State-supported research institutions. To understand these methods better it is well to know something about the flowering habit and the floral characters of the onion plant.

Inflorescence and Pollination

When mother bulbs are planted in the late fall or winter the rudimentary parts of the flower stalks do not differentiate until the following spring, and it is usually 3 or 4 weeks after differentiation before the flower parts emerge through the sheaths that surround them. The flower stem elongates rapidly and may develop to a height of 5 or 6 feet but usually not more than 3 or 4 feet. The number of flower stems per plant ranges from 1 to 20 or more, depending on the size of mother bulb, the variety, and climatic conditions.

The flowers are borne in simple umbels at the upper end of the elongated stalk, the young buds being enclosed within a papery bract which is split open by pressure of the developing buds shortly before the flowers open. The number of flowers per umbel may range from 50 or less to 2,000 or more. The flowers have six perianth lobes or floral leaves in two whorls of three each and six stamens in two whorls of three each. The pistil has a three-celled ovary with two ovules in each cell. The anthers of the three inner stamens are the first to open, shedding their pollen one after the other at irregular intervals,

after which the anthers of the outer whorl of stamens open, also at irregular intervals (fig. 1). The pollen of a single flower is shed before the stigma becomes receptive, and the process is usually completed in 24 to 36 hours. The style is approximately 1 mm (0.039 inch) long when the flower first opens, not reaching its maximum length of about 5 mm (0.197 inch) until a day or two after all the pollen from that flower has been shed. The flowers of a single head may continue to open over a period of 2 weeks or longer, and a plant may be in flower for 30 days or more.

Most of the pollen is shed between 9 a. m. and 5 p. m. Pollination is effected mainly by insects that go from flower to flower and visit the nectaries at the base of the three inner stamens. Interpollination among flowers of the same umbel is no doubt of frequent occurrence, as the same insect has been observed to visit many flowers on an umbel before leaving. In the onion, however, cross-pollination is the rule.

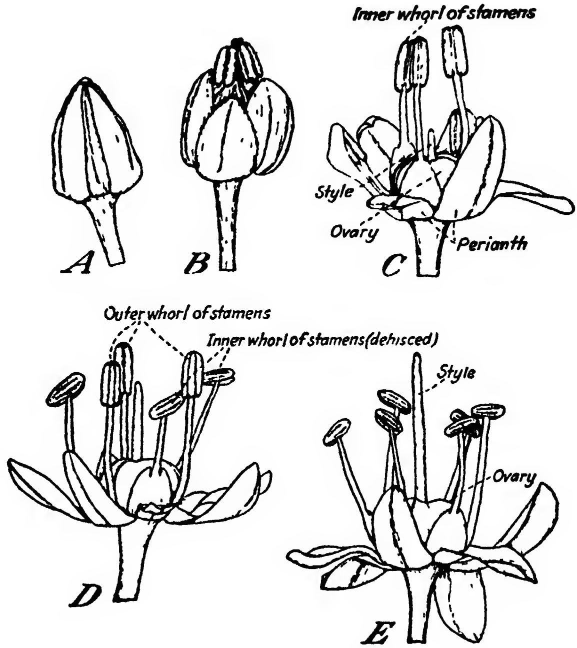

Figure 1.—Method of flower opening and pollen shedding in the onion: *A*, Flower bud just before opening; *B*, the two outer whorls of floral organs expanding and the inner whorl of stamens elongating; *C*, just before the shedding of the pollen by the inner whorl of stamens; note the short style; *D*, the three stamens of the inner whorl have shed their pollen and the three of the outer whorl have elongated; *E*, all six stamens have shed their pollen; note the long style, now receptive. (From Jones and Rosa, *Truck Crop Plants*.)

Selfing an Aid in Onion Breeding

In the onion selfing or inbreeding, accomplished when a plant is self-pollinated, is not an end in itself but merely one of the tools used in the breeding program. Inbreeding in the onion is almost always accompanied by a loss of vigor for a number of generations. However, it permits many undesirable characters that have been carried along in the germ plasm, perhaps covered up by dominant traits, to express themselves, so that the lines possessing them can be rogued out. The main purpose of inbreeding is to develop lines that will breed true for certain characters. Selfing is accomplished in the onion by covering the entire umbel to prevent contamination with foreign pollen. When the first flower opens on an umbel the entire inflorescence is enclosed within a 1-pound manila

paper bag and tied closely so that there will be a crowding of the flowers within the bag (fig. 2). If the umbels are small, as is usually the case after several generations of inbreeding, a number of heads can be enclosed in the same bag, thereby crowding flowers and facilitating pollination. Once each day toward evening, when the pollen is dry, the bags are tapped rather vigorously to help circulate the pollen within.

Breeding Program with Inbred Lines

Much of the improvement work, especially by commercial seedsmen, has as its object the freeing of varieties from plants that are off-type and making a variety or strain uniform for important commercial

Figure 2.—Method of self-pollinating onions. Inflorescences are enclosed in 1-pound manila paper bags.

characters. This can best be done by selecting bulbs that are true to type, selfing to secure uniform and true breeding lines, and finally massing the apparently similar selected inbred lines to bring about crossing, which will restore vigor. Such a program follows:

First year.—Select a large number of commercial bulbs that approach the ideal for the variety; the larger the number the better the chance of securing desirable lines. Plant the selected mother bulbs in late fall, winter, or early spring, depending upon the locality.

Second year.—Self-pollinate as described in the section on selfing.

Third year.—Grow progenies of all selfed plants separately. Destroy undesirable lines during the growing season, or at harvest time, or upon their removal from storage. Retain the best bulbs in 25 or more of the most outstanding lines and plant for selfing and open-pollination.

Fourth year.—Half of the umbels on each plant are selfed and the others are allowed to open-pollinate. By following this procedure it is possible to secure a

supply of open-pollinated seed of superior quality that can be increased rapidly to quantity production. For practical purposes it is usually best not to inbreed more than two generations, because as a rule the plant is greatly weakened and it is difficult to secure a quantity of seed.

Fifth year.—Grow the progenies that were selfed in the fourth year separately and again select the best bulbs from at least 25 lines for open-pollination.

Sixth year.—Group all selections and plant them in the field so that the maximum amount of crossing between unrelated lines will occur. Mass the seed and increase.

Use of Flies to Facilitate Crossing

When new characters are to be incorporated in a variety, as is necessary in most cases when breeding for disease resistance, then the breeder must resort to crossing. Plants to be used for crossing are

Figure 3.—Method of introducing flies into small pollination cages. The cages are made of cheesecloth stretched over wire frames and tied at both ends. (Courtesy California Agricultural Experiment Station.)

usually set 2 to 3 feet apart in the row to allow plenty of room for manipulation of the small cage to be described later. The umbels are bagged as soon as the first flower opens. At first only a few flowers on an umbel open daily, but the number increases until full bloom, when 50 or more may open in a single day. These early flowers are removed several times daily from the umbel of the female parent. When the weather is hot they must be removed often because the anthers shed their pollen very soon after a flower opens. When blossoming is at its peak, open flowers are no longer removed but are emasculated and used for crossing. Umbels must be examined frequently and the anthers removed from the open flowers before the pollen is shed to prevent contamination of the umbel.

When enough flowers have been emasculated, the remaining buds of the inflorescence are removed. The emasculated and disbudded umbel is then enclosed under a small cheesecloth cage as shown in figure 3. The inflorescence of the male, or pollen, parent, which has also been kept covered to prevent pollen contamination, is cut off and enclosed within the same cage, with the base of the stalk standing in a bottle of water. When handled in this manner the flowers continue to open and shed pollen for a week or more. Flies are added to the cage to do the pollinating. This technique, as compared with hand-pollination, makes it possible to multiply greatly the number of crosses, and also to secure a higher percentage of seed setting. To be certain that flies are free from foreign pollen, it is necessary to raise them under controlled conditions.

At Davis, Calif., where considerable onion-breeding work is under way, a technique for the growing of flies for pollination purposes has been developed. Lungs of beef, upon which the adult blowflies lay their eggs, are exposed on tables in the open. The lungs are under a roof to provide protection from a high temperature and rain, which might kill many of the larvae. Within a few days the larvae hatch and begin to feed. When mature they begin to wander about to find a place to pupate, at which time they are trapped by attaching a trough along the side of the table into which the larvae fall. A pail, containing a small amount of finely screened sand, is suspended at the end of the trough. Once each day the pail is removed and replaced by another so that each pail will contain larvae of approximately the same age. The larvae soon burrow into the sand to pupate, and later the pupae are separated from the sand by screening. The pupae are held at room temperature and are placed in a small screen cage before the adults emerge (fig. 3). Each cage, measuring about 6 by 6 inches, has a cone-shaped top, at the apex of which is a small opening closed by a cork. As the flies hatch they gradually move up into the cone. When used in pollinating, the cone is inserted into the lower end of the cloth cage containing the two umbels, the cork is removed, and as many flies as needed are allowed to escape into the cage. They soon begin to feed and in doing this carry pollen from flower to flower and accomplish pollination.

It is often desirable to accumulate mature pupae in order to have a good supply on hand for the peak of the pollinating season. They can be kept for several weeks at about 45° F. It is best not to store them at this temperature until the adults are almost ready to emerge, otherwise fewer of them will emerge. Also, the flies appear to be less active when the pupae are stored early in the pupation period.

BREEDING FOR RESISTANCE TO DISEASE

PINK root of onion, caused by the fungus *Phoma terrestris* Hansen, is a major disease in many onion-growing districts, especially of the South and West. Porter and Jones (*18*), working in California, found that Sweet Spanish was slightly resistant to pink root and that the Japanese onion, *Allium fistulosum*, Nebuka type, was very resistant. In California, Australian Brown No. 17, a single plant selection, is somewhat more resistant than the commercial variety from which it was isolated, and Sweet Spanish No. 35, another single plant

selection, is also more resistant than the commercial variety. Felix (*7*) has also reported that Winterhecke and White Welsh, varieties of *A. fistulosum*, as well as different strains of Nebuka (Natsu-negi Nebuka, Senj-negi Nebuka, Tokyo-Nebuka, and Iwatsuki), are resistant to pink root.

The various types of *Allium fistulosum* have little commercial importance in the United States, but it would be desirable to have certain insect- and disease-resistant characters they possess incorporated in varieties of *A. cepa*. With these objects in view, Emsweller and Jones (*3*) have made a large number of crosses between some of the Nebuka types and many varieties of *A. cepa*. First-generation hybrids of Yellow Globe Danvers × Nebuka and Nebuka × Australian Brown have been grown on soil heavily infested with the pink root organism; the roots showed some pink, but the plants apparently were not checked in their growth. The Australian Brown variety has proved very susceptible to pink root, yet the hybrid grew vigorously on infested soil throughout the season. Back crosses have been made to the Australian Brown variety, but readings have not as yet been made on resistance.

The smut disease, caused by the fungus *Urocystis cepulae* Frost, is present in most of the onion-growing districts of the North. Formaldehyde applied in the row at time of seeding is a satisfactory control measure, but the cost of this treatment could be eliminated by the development of resistant varieties. In 1925 Anderson (*1*) suggested the use of Winterhecke as the logical parent for the breeding of a smut-resistant onion by crossing. He states that it is almost immune to smut, and by his description of the variety one is led to believe that it is the Nebuka type of *Allium fistulosum*. In 1932 the writer sent seed of the Nebuka to A. G. Newhall, of Cornell University, who tested the seedlings under epidemic conditions and found them to be practically immune to smut. Breeding work is under way at present looking toward control by the use of resistant varieties. Progenies involve crosses between the two species, *A. cepa* and *A. fistulosum*. Only a few first-generation hybrid plants were secured, and these have been self-sterile. Back crosses have been made to both parents, however, but as yet these progenies have not been subjected to resistance tests.

Mildew, caused by the fungus *Peronospora schleideni* Unger, is one of the most destructive diseases to the onion seed crop. In California losses may run as high as 80 percent in some seasons. Several onion strains that are highly resistant to mildew have been isolated by investigators of the California Agricultural Experiment Station. One of these is a male-sterile strain of Italian Red, pedigree 13–53, the leaves of which are highly resistant and the seed stems apparently immune. Many progenies are now being tested under epidemic conditions.

A disease called smudge, caused by the fungus *Colletotrichum circinans* (Berk.) Vogl., does considerable damage to the storage crop of the North by causing bulb shrinkage and premature sprouting. Walker, Link, and Angell (*23*) have shown that pigmented varieties of onions are resistant to smudge, while the white are not. On pigmented onions the disease is confined mainly to the neck. Resist-

ance is probably due mainly to the presence of protocatechuic acid—one of the carbolic acids—which is in some way closely associated with the yellow and red pigments in the dry outer scales of the bulb. Insofar as known, this is the first case where resistance to a certain disease has been shown to be due to a definite chemical constituent. Rieman (*20*), in a study of the relation of pigmentation to disease resistance, states that the genes *W* (red) and *Wy* (yellow), which are responsible for the production of the red and yellow pigments, are also responsible for the production of protocatechuic acid. Whether or not resistance can be incorporated in the true-breeding white varieties of onions remains to be determined.

According to Walker (*22*), pigmented onions are also more resistant to the invasion of certain species of the fungus *Botrytis* (*B. allii* Munn, *B. squamosa* Walker, and *B. byssoidea* Walker). He states that resistance in colored bulbs appears to be due to a water-soluble toxic substance in the outer scales that excludes the fungi. Colored bulbs are not resistant once infection is established.

Yellow dwarf is a virus disease of onion that causes a characteristic yellowing, wrinkling, twisting, and drooping of the leaves and dwarfing of the plant. This disease was prevalent for a time in the Pleasant Valley onion district of Iowa and has also been reported in other districts. In a field test of 34 varieties in 1929 Henderson (*10*) found that Sweet Spanish was the only variety showing marked resistance. Plants of this variety did not contract the disease when inoculated artificially and furthermore did not carry the disease in a masked form. It will be recalled that this same variety carries considerable resistance to thrips and to pink root.

BREEDING FOR RESISTANCE TO INSECTS (THRIPS)

THRIPS are present wherever onions are grown, and it is estimated that they cause more loss than all other insect pests and diseases combined. Satisfactory chemical control has thus far been impossible, because a large number of thrips are always protected between the inner leaves of the plant, the pupal stage is spent in the soil, the species is very prolific, the generations overlap, natural parasites are lacking, and other host plants are numerous. The unsatisfactory control secured by chemical means necessitates a mode of attack different from that made in the past. Jones, Bailey, and Emsweller (*11*) showed that certain varieties and species of onion have definite resistance to thrips. Among the most resistant are White Persian, Nebuka, California Early Red, Early Grano, and Sweet Spanish. Counts made in 1932 and 1933 showed that the varieties used were resistant in about the same order in both years, so that certain of their characters evidently influenced the size of the thrips population per plant.

The White Persian variety (P. I. 86279), obtained from Persia through the Division of Plant Exploration and Introduction of the Bureau of Plant Industry, showed by far the most resistance (fig. 4). The resistance of this variety seems to be determined by certain growth characters, which help to hold the thrips population to a minimum, and perhaps by anatomical and physiological characters, which help the plant to withstand injury. The shape of the leaves is probably of importance in restricting the thrips population. In most

varieties the leaf blades have a flat side; in opposite leaves these sides are face to face and the young leaves are closely pressed together so that the larvae are protected against insect enemies and adverse weather conditions. In White Persian the leaves are almost circular in cross section and protection is reduced to a minimum. The wide angle between the two innermost leaves, especially in the young plant, is another White Persian character that helps to restrict the thrips population by reducing their protection to a minimum. Still another character, probably of some importance, is the greater vertical distance between the leaf blades, each new leaf extending its sheath farther beyond the one encircling it than in other known cultivated varieties. This habit of growth produces an extremely long sheath column.

Figure 4.- Thrips-resistant onions. The three rows to the left are the variety White Persian (P. I. 86279); to the right are Australian Brown. Note the serious damage done by thrips to the latter variety and the freedom of the White Persian from injury. (From Jones, Bailey, and Emsweller, *11*.)

If commercial varieties of onions had these leaf characters the thrips population per plant would be reduced to a minimum and it would be possible to secure more efficient control by spraying or dusting. The shape and habit of leaf growth in the White Persian help to restrict the number of thrips; other characters help the plants to withstand injury, but these are as yet undetermined. Maughan and MacLeod (*16*) are of the opinion that avoidance of the plant by the thrips, the angle of contact of the leaves, the stage of growth of the plants, the ability of the plant tissues to recover from injury, and probably other influences have a bearing on resistance.

CROSSES BETWEEN SPECIES

THE Nebuka type of *Allium fistulosum* has very little commercial importance in the United States at the present time, but because of its resistance to various diseases, insects, and adverse climatic condi-

tions it has become a valuable source of breeding material. Crosses have been made between Nebuka and various important commercial varieties of *A. cepa* by Emsweller and Jones (*3*), with the object of incorporating certain resistance factors possessed by Nebuka into commercial varieties of *A. cepa*. This species cross is rather difficult to make, but with the aid of flies considerable numbers of first-generation hybrid seed have been produced.

The Nebuka types are nonbulbing; the hybrids between them and *Allium cepa* are intermediate in bulbing habit (fig. 5). Nebuka is a perennial; *A. cepa* is a biennial; the hybrids between the two are perennials, the tops remaining erect and the plants continuing to grow

Figure 5.—*A*, Commonly cultivated bulbing type of onion, *Allium cepa*, variety Yellow Globe Danvers; *B*, Japanese onion, *A. fistulosum*, Nebuka type; *C*, first-generation hybrid between the two. This species cross gives great promise for breeding onions resistant to diseases and other adverse conditions (*3*).

as long as weather conditions are favorable. Although seed is produced in abundance by Nebuka, the plants continue to form divisions at the base, and these can be used for propagation. In date of flowering the hybrids are intermediate between the two parents. Nebuka is usually in bloom 6 or 7 weeks before *A. cepa*. Blossoming occurs irregularly over the entire inflorescence throughout the flowering period in *A. cepa*, but in Nebuka the terminal flowers open first and blossoming proceeds progressively toward the base. In the hybrid the terminal flowers are the first to open, although with less precision than in Nebuka; then a wave of opening extends toward the base, but this does not terminate the blooming of the umbel, for blossoming then continues for a time over the entire inflorescence as it occurs in *A. cepa*. In *A. cepa* the perianth becomes fully expanded; in *A. fistulosum* it remains erect; the hybrid resembles the *fistulosum* parent very

closely. In the Nebuka varieties the leaves are circular in cross section, whereas in most varieties of *A. cepa* the leaf blade is semicircular; in the hybrid the semicircular type of leaf is dominant. Under similar growing conditions the hybrids show more vigor than either of the parents. They multiply rapidly by subdivisions at the base, and should be able to increase and perpetuate themselves under natural conditions. The hybrids are practically self-sterile; they are, however, useful as pollen parents for back crossing to both *A. cepa* and *A. fistulosum*. When the percentage of functional reproductive bodies is very small, normal sperm cells are naturally more numerous than normal egg cells, because of the much larger total number produced.

PREMATURE SEEDING AND FREEZING INJURY

PREMATURE seeding (bolting) occasionally causes heavy losses in the early crop of the South and in those districts where an intermediate crop is grown from dry sets or transplants. In central California the percentage of bolting is high when a cool spring follows a warm fall. A warm fall causes a large plant to develop. This size and cool spring weather provide the proper combination of conditions for bolting, according to Jones, Poole, and Emsweller (*13*). Because of the lower temperatures prevailing along the central California coast, bolting is more prevalent there than in the interior valleys, making it an ideal place to select and breed nonbolting strains that may be useful elsewhere. The difference in bolting habit between varieties is clearly brought out by comparable plantings made in five locations in California during the season 1934–35. A few of the varieties, with the percentages of bolting, follow: Babosa, 73; Lord Howe Island, 66; Earliest Express, 66; Early Grano, 63; Blood Red Rocco, 51; White Italian Tripoli, 42; California Early Red, 19; and Italian Red, 17. A selection out of Stockton Yellow Globe, strain 36–40, gave only 2 percent of bolters, while a selection out of Stockton Yellow, strain 21–1–3–4–S_3, inbred for six generations, was entirely nonbolting. These highly nonbolting strains are being used in crosses to incorporate this character into varieties that are prone to seed prematurely when conditions favor.

Magruder and Hawthorn (*15*) found varietal differences in resistance to freezing injury, the soft-textured types of onion, such as Yellow Bermuda, Crystal Wax, California Early Red, Extra Early Yellow, and Italian Red, being the most susceptible.

GARLIC

THE culture of garlic (*Allium sativum*), like that of onion, dates back to time immemorial. Vavilov (*21*) gives middle Asia as the primary center of origin and the Mediterranean region as the secondary center. From these centers the culture of the plant has become worldwide. It is highly prized for seasoning. Large collections of foreign varieties of garlic have been secured by several States through the Division of Plant Exploration and Introduction. These varieties vary widely in such characters as number, size, keeping quality, color, and pungency of the cloves, time of maturity, yield, resistance to thrips, and extent of flower development. On some varieties flower stems have never

been observed to develop; on others they reach a height of 4 to 6 feet and contain umbels with a thousand or more flowers; and between these two extremes there seem to exist all possible gradations. For some reason, at present unknown, all varieties fail to produce seed. Even on the profusely blooming Spanish and Creole types seeds have never been observed. Because of the lack of sexual reproduction, improvement must be secured entirely through the selection of bud mutations.

CYTOLOGY AND GENETICS OF THE ONION [2]

THE onion has long been used as a source of material for studying the behavior of the somatic and meiotic chromosomes. Emsweller and Jones (*4*) studied the morphology of the chromosomes of the two species *Allium cepa* and *A. fistulosum*, to develop a method by which the chromosomes of a genom could be identified, avoiding so far as possible the use of total chromosome length. Chromosomes were observed at the first division of the microspore, at which time they are well spaced and only one of each pair is present. The length of any individual chromosome when measured in different cells is not constant because of lack of uniformity in stage of contraction and in fixation. The constriction region is assumed to be located at a definite point on the chromosome, making it possible at least at late metaphase to recognize two arms, and a constant index figure can be calculated by dividing the length of the short arm by that of the long arm. Emsweller and Jones (*5*) have shown also that the type of chiasma is gene-controlled. In *A. fistulosum* the chiasmata, at the first metaphase, are localized at the constriction region, while in *A cepa* the chiasmata are placed at random. In the first generation the chiasmata were at random as in the *cepa* parent. In back crosses to *A. fistulosum* chiasmata were localized in 10 plants and at random in 7, indicating that the difference in type of chiasma is controlled by a single gene, the localized type being recessive.

In a genetic analysis of the three bulb colors, red, yellow, and white, commonly present in the cultivated onion, Rieman (*20*) found that it was necessary to postulate five different genes to account for the results secured—*I*, a gene for incomplete inhibition of color; *i*, a gene allowing expression of color; *W*, a gene for red pigment; *Wy*, a gene for yellow pigment; and *w*, a gene for white. The gene inhibiting color, *I*, is dominant to its recessive allelomorph, *i*. The heterozygous factor pair, *Ii*, produces red-necked and cream-colored bulbs in the presence of the color genes *W* or *Wy*. The latter and the factor pair *Ii* are inherited independently. The gene for red, *W*, is dominant to the gene for yellow, *Wy*, and the gene for white, *w*. The color genes are considered to be multiple allelomorphs.

Rasmusson (*19*) observed several abnormalities in chlorophyll development, white, yellow, chlorina, and T-chlorina. The white and yellow seedlings soon die. The chlorina form is yellowish at first but later may become greenish. The T-chlorina is somewhat paler in color than the chlorina and soon perishes. Some green plants when selfed yielded progeny in the theoretical green to white ratio of 15:1. Green and yellow, green and chlorina, and green and

[2] This section is written primarily for students and others professionally interested in genetics or breeding.

T-chlorina in each case occurred in a ratio of 3:1, but in some cases green and chlorina were in a ratio close to 15:1. Green:chlorina:white occurred in the ratio of 9:3:4, as did green:chlorina:yellow.

BREEDING AND IMPROVEMENT OF PEAS AND BEANS

B. L. WADE, Senior Geneticist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

PEAS

NATURALISTS have been interested in *Pisum* for several hundred years, and there are many unmistakable references to peas in the writings of the old Greeks and Romans. Columbus is reported to have grown peas on Isabella Island in 1493, and General Sullivan destroyed the growing peas of the Indians in western New York in 1779.

Pickering (*50*)[1] states that of the culinary vegetables *Pisum sativum* is the only kind that can with any certainty be traced back to the Stone Age. It was uncommon for peas to be eaten in other ways than as dry, cooked seeds before 1700.

Much of the history of *Pisum* has been well reviewed by Hedrick, Hall, Hawthorn, and Berger (*14*). Ruellius in 1536 was the first to distinguish between garden and field peas. Since *Pisum sativum* L., the garden pea, and *P. arvense* L., the field pea, are completely cross-fertile, the distinction seems entirely artificial, and most writers now consider both types under *P. sativum*. In addition some varieties of garden and canning peas (unquestionably *P. sativum*) are used extensively for field peas.

It is noteworthy that peas were the first crop with which controlled breeding work for the production of new varieties was begun, and also that they were the crop with which Mendel conducted his historic experiments, which were the beginning of the modern science of genetics.

Vavilov (*80*) indicates that peas probably had their origin in Ethiopia, with secondary centers of diversity in Mediterranean Europe and in southwestern and central Asia. Although many forms are known in the Mediterranean region, peas have never been of much importance in that area. Farther north, in England, peas have reached their greatest perfection, and they are an important crop in Scandinavia, Germany the Netherlands, and France. The Union of Soviet Socialist Republics at the present time probably surpasses all other countries in the production of peas, mostly dry edible seeds. In 1929 the acreage of peas for grain in the Union of Soviet Socialist Republics was 1,435,750 acres. The estimated crop for 1931 was 2,750,000 acres.[2] Further increases are anticipated. The United States pea acreage for all purposes probably does not exceed 1,000,000 acres.

[1] Italic numbers in parentheses refer to Literature Cited, p 277

[2] Communication from R K Bonnett, Moscow, Idaho, 1931

The pea is a vegetable easily introduced in most places where the climate is favorable. The plants of many varieties are cold-hardy and will survive a winter under a snow covering. If slightly frozen they will put out new shoots when the weather becomes warmer. The blossoms are not particularly cold-tolerant and will survive only a light frost. Peas do not thrive very well in warm weather, so their culture in the southern and southwestern United States is confined largely to the winter and spring months. In the southern part of the Union of Soviet Socialist Republics, where summer quickly follows winter, peas are grown to a limited extent. In the north-central part of the Union of Soviet Socialist Republics, east of Leningrad, west of Moscow, and in southwestern Siberia they are a very important crop.

Peas may be divided into at least five classes according to use: (1) Forage or green-manure crops, (2) dry, edible seeds, (3) market-garden or green shelling peas, (4) canning peas, and (5) edible-podded peas, which have no lining membrane in the pod, a condition that has been traced to two genes. The Union of Soviet Socialist Republics and the southern United States devote large acreages to forage and green-manure crops. Nearly all the important pea-producing countries devote large areas to the production of seed for food and feedstuffs, especially the Union of Soviet Socialist Republics, Germany, the Netherlands, and the area around Spokane, Wash., in the United States. Classes 1 and 2 above are usually referred to as field peas. California produces more than two-thirds of the market-garden or truck peas grown in the United States, of which the annual acreage is now well over 100,000 acres.

The climate of England is especially favorable to the production of large-podded market-garden peas of high quality.

Lately the preservation of shelled green peas by freezing has become important in some parts of the United States, particularly the Pacific Northwest. This industry uses both market-garden and canning varieties, but several seedsmen are now working to develop varieties especially adapted to freezing.

THE *most highly evolved pea variety so far produced by breeders is probably Laxton's Progress. It has a very dwarf vine with a zigzag stem, which makes it sturdy and upright; dark-green foliage; and large, straight, dark-green, pointed pods, from which the peas can be shelled readily. Each of these characteristics is important to growers and each received attention in breeding. The most notable characteristic of Progress, however, is that it begins to bloom at the eighth or ninth node on the stem. This may not seem significant to the inexperienced, but to pea farmers it is worth years of difficult breeding work; for it means that Progress is a few days ahead of its nearest rival in excellence, Hundredfold, which does not begin to bloom until the ninth or tenth node.*

The United States cans annually from 12,000,000 to 20,000,000 cases of peas,[3] mainly in the States of Wisconsin, New York, Maryland, Michigan, and Washington. The canning of peas is not an extensive industry in any other country at present. Edible-podded peas are widely grown in continental Europe. They are for the most part more tolerant to heat than are other peas and have now become a rather common vegetable in Hawaii and southern China. In the continental United States they are practically limited to home gardens.

Origin of the Older Varieties

Thomas Andrew Knight, of Downton Castle, Wiltshire, England, the first great hybridizer, began his work with peas in 1787. Some of his varieties are still used, and they have been the foundation breeding stock for most modern pea varieties.

In 1822 John Goss published a paper in which he recognized the dominance of yellow cotyledons and that green segregates from his crosses bred true. If he had carried his observations a little farther he would have antedated Mendel's discoveries by some 40 years.

Succeeding Knight, many famous pea breeders began their work in England. About 1860 McLean, of Colchester, produced Little Gem and his important Advancer, from which the American varieties Abundance and Perfection were derived. Thomas Laxton bred the variety that bears his name, introducing it in 1898. Laxton Bros. later produced Laxtonian about 1907, and Progress in 1921.

Culverwell originated Telegraph, a smooth-seeded variety with long pods and a tall vine, some time before 1877. It became very popular both in England and in the United States. Telephone, a wrinkled-seeded strain of Telegraph, was derived from Telegraph by Carter in 1878, and has largely replaced it, probably on account of its much better quality. Alderman, introduced by Laxton about 1891, has largely replaced Telephone in the United States, probably because of the demand for darker pods.

Several English seed companies have for at least 50 years poured a continuous stream of new varieties into the markets of the world. Most of these have been successful only in England, but such a diversity of varieties has been supplied that most countries find themselves using a number of varieties that originated in England. The principal English seed companies contributing to pea improvement have been Laxton Bros., Sutton & Sons, Carter & Co., and Hurst & Co

All American varieties are undoubtedly similar to English varieties and in many cases confusion exists as to the origin of a given variety. Alaska was introduced as an American variety by A. B. Cleveland about 1880. It is so similar to the English variety Earliest of All, a cross of Ringleader×Little Gem, introduced in 1881 by Laxton, that these two varieties are now indistinguishable. Alaska is a smooth-seeded, very early, straight-stemmed variety with light-green pods and foliage, which typically begins blooming at the eighth node.

Dwarf Telephone as now grown is a midseason variety blooming at about the fourteenth node. The vine is a sturdy dwarf with a zigzag stem, and the pods and foliage are light green. The pods are long and pointed. Introduced in 1888, the variety is now inextricably

[3] A case equals 2 dozen 20-ounce cans.

Origin and Evaluation of New Varieties and Strains

The Wisconsin Agricultural Experiment Station group working with canning peas have greatly influenced the trend in the industry. E. J. Delwiche has been prominent in this work and has contributed at least 11 strains, of which Badger (1921), a variety like Perfection, was the first introduction. Badger is of exceptionally high quality, but the canning trend away from small seeds and susceptibility to wilt has prevented its general use. Horal (1923), a small-vined Perfection type, one of the heaviest-yielding peas known to the canning industry, failed to achieve popularity because of its very decided lack of quality coupled with small seed size. Alcross and No. 19 strains of Alaska have been of value in breeding homozygous wilt-resistant strains of Alaska peas. They are still grown to a considerable extent, and some of the completely wilt-resistant strains of Alaska on the market have been selected from them. Ashford (1924) is an exceptionally good strain of Horsford, but it is later than Perfection, and therefore the demand for it is very limited. Wisconsin Early Sweet (1931) is a vigorous wilt-resistant type approaching Surprise in quality and having the hardiness of Alaska. It promises to become a very important variety. Wisconsin Perfection (1933) has achieved some popularity on account of its hardiness and wilt resistance.

The Canners Seed Corporation has introduced several new strains of peas since 1930. These have all resulted from the breeding work of E. J. Renard. All introductions by this company have been pure (homozygous) for wilt resistance and were bred especially for adaptation to conditions in Wisconsin. Wilt-resistant Perfection (1930), wilt-resistant Alaska (1930), and wilt-resistant Early Perfection (1933) have been very favorably received by the canning trade. The popularity of large-seeded Perfection and Improved Wales will depend on the trend of the canning industry toward or away from large-seeded types

The Washburn-Wilson Seed Co. has introduced several strains of completely wilt-resistant peas since 1932. These are for the most part the result of breeding work carried on by the writer. The most successful of these seem to be Walah (1932), from Prince of Wales; Alah (1932), which is a wilt-resistant Alaska; and Mardelah (1935), a wilt-resistant Surprise type.

C. E. Temple, of the Maryland Agricultural Experiment Station, has originated a strain of Alaska that does well under conditions existing in Maryland and adjoining States. It is resistant to fusarium wilt (caused by *Fusarium orthoceras* Appel and Wr. var. *pisi* Linford) and possibly to certain other diseases.

Stuart F. Smith, of the Sioux City Seed Co., has produced wilt-resistant strains similar to Alaska and Perfection. M. C. Parker, of the Gallatin Valley Seed Co., is breeding peas for fusarium wilt resistance, types for freezing, and types with multiple pods.

It would appear from the emphasis on wilt resistance that fusarium wilt has been of great importance in the United States. To a considerable extent it has been important, even the limiting factor in certain areas. Probably the most interesting thing in connection with the work on fusarium wilt has been the general adoption of pure-

line breeding by the seed companies. It was found that most stocks of partially wilt-resistant strains did not give good canning results, on account of the mixture of prematurely ripened peas from susceptible plants with the normal peas from the resistant plants. After it was found that pure lines were highly satisfactory in the wilt work, pure-line methods were used in connection with other seed stocks, so that the standards of the industry with regard to rogues have been very definitely raised.

Much confusion usually exists in the seed industry as to the exact identity of strains. It is not improbable that some one strain of wilt-resistant Alaska or other varieties may come to be considered of outstanding merit. However, with the lapse of time and the tendency to substitute similar things for each other, confusion will arise as to the actual strain employed. Many companies have found that wilt-resistant Alaska and wilt-resistant Perfection are entirely satisfactory as canning peas and cannot be distinguished in any definite way from corresponding susceptible biotypes except in reaction to wilt, so that they feel justified in carrying only one strain of each major variety. New York State apparently does not have a wilt problem, but many of the Alaska and Perfection stocks delivered in that State are wilt-resistant.

The future canning types for this country are rather unpredictable, but it seems likely that early peas with stems like Alaska or Surprise, and later peas with heavier stems like Perfection, will be in demand. Large-seeded strains are being sought for the canning of ungraded "sweets", but so far they have not given entirely satisfactory yields. Resistance to diseases other than wilt, to insects, and to adverse weather conditions all are problems that will be worked on in the near future by plant breeders, and in some cases such work is already under way. Searles, at the Wisconsin Agricultural Experiment Station, is doing some work on tolerance of pea varieties to aphid injuries.

Among the market-garden types, Progress (Laxton Bros., 1921) is the most important variety. Hundredfold (Sutton, 1910) is next in importance. These two varieties have largely replaced similar varieties like Laxtonian, Blue Bantam, Pioneer, and Peter Pan. Giant Stride (Carter, 1916) is now probably third in importance. It has largely replaced Dwarf Telephone and Stratagem in the western United States. As introduced it was quite a variable strain. Asgrow No. 40 and Stridah are pure-line selections from Giant Stride or similar material introduced in 1930 and 1931. Recently the United States Department of Agriculture, partly in cooperation with the California Agricultural Experiment Station, has proceeded with crosses between Giant Stride and Progress in which desirable early Progress and Hundredfold types have been selected for resistance to strains of *Fusarium*.

Seed stocks handled under the name of Alderman consist essentially of two types. One type is true Alderman (Laxton, about 1891) and is extensively grown in home gardens where a variety adapted to trellising is desired, and to a limited extent in commercial market-garden areas. The other type is common in the truck-farming areas of the West and is either Quite Content (Carter, 1906) or a derivation

from a cross of Alderman with Quite Content. The largest pods and most fancy packs of market peas obtained in the United States are made from this second type of Alderman, which really deserves a name of its own. Sometimes it is referred to as long-pod Alderman, or Alderman with some geographic designation. The best way of differentiating between the Alderman types is by noting pod-wall thickness. The old type of Alderman has a thin pod wall and the new type has a much thicker pod wall.

Early Gilbo (Rogers, about 1934) is an exceptionally promising variety midway in season between Hundredfold and Giant Stride. The pods are straight, well-filled, approximately as large as those of Giant Stride, and moderately thick walled.

Gradus, Thomas Laxton, and World Record are popular in certain areas in the eastern United States, but the pods are so small that western shippers do not use them. These are all early, straight-stemmed varieties blooming at the eighth to tenth nodes. Thomas Laxton has blunt pods, the other two have pointed pods.

Many American seed companies have contributed to the introduction or breeding of superior varieties and strains of peas. Among these should be mentioned Associated Seed Growers, Inc., and their predecessor firms, the Everett B. Clark Seed Co., the John H. Allan Seed Co., and N. B. Keeney & Sons; the Ferry-Morse Seed Co. and their predecessor firms, D. M. Ferry & Co. and C. C. Morse & Co.; the Rogers Bros. Seed Co.; the Washburn-Wilson Seed Co.; the Gallatin Valley Seed Co. and its predecessor firm, the Davis Seed Co.; the Canners Seed Corporation; the Sioux City Seed Co.; W. Atlee Burpee & Co.; the Jerome B. Rice Seed Co.; Francis C. Stokes & Co. and their predecessor firms; the Chas. H. Lilly Co.; the Livingston Seed Co., and Vaughn's Seed Store.

SNAP BEANS

History and Use

Beans (*Phaseolus vulgaris* L.) were introduced from the Americas to Europe and Asia, where they early became popular. They were mentioned in Europe about 1542, and by 1616 a large number of varieties of different types were described. Hedrick, Tapley, Van Eseltine, and Enzie (*15*) have given a very satisfactory summary of the early history of beans and descriptions of varieties now grown or once grown in the United States. The most extensive previous studies of bean varieties were made by Irish (*17*), Tracy (*77*), and Jarvis (*18*).

Beans may be divided into three major classes according to form in which they are harvested and used—(1) dry shell, (2) green shell, (3) snap or green beans. There is some overlapping of these groups. For instance, Canadian Wonder is thought of as a dry shell bean in this country but is considered a good snap bean in parts of the British Empire. Low Champion as used falls in all three categories. Snap bean varieties may be further divided into (a) market garden, (b) home garden, and (c) canning beans, but distinctions on such a basis are not particularly valid, since most of the canning beans are frequently used for the other two purposes. Most of the present discussion will be concerned with snap bean varieties and their development.

Beans are also classified according to type of vine and pods. A bush bean is a type in which the inflorescence is at the tip of the plant; when it appears, the plant stops growing. In a pole bean, on the other hand, the flowers are along the stem, which continues to grow indefinitely, its ultimate length depending on environmental conditions. All bean pods are green when they are very small, but some turn white, yellow, or crystal [4] as they approach an edible stage. The latter types are called wax beans. Pole beans are mostly used for home gardens. Wax beans are everywhere less popular than green, but they are used for canning, shipping, and home gardens. Since wax pods readily show spots, there has been some discrimination against them in sections where pod-spotting diseases are common. From a shipper's standpoint beans are also classified as flat or round. Beans heart-shaped or oval in cross section are usually classed with the round group, and any pod with a diameter in one direction less than 80 percent of the diameter at right angles to it is considered flat.

At the present time Florida produces well over half the shipping crop of market-garden snap beans. New York, Maryland, Wisconsin, Michigan, and Colorado produce a large part of the crop for canning.

Origin of the Older Varieties

An interest in early bean varieties with stringless pods gave the initial impetus to American bean breeding about 1890. Previous to that time seed companies had given but scant attention to bean breeding, apparently being content to introduce a selection made by a farmer or a variety that had become common in some farming community. White Kidney (shell), Dutch Caseknife, Lazy Wife (pole), Early Yellow, Six Weeks, and Mohawk go back too far in horticultural history to be traced with any degree of certainty. Wax beans seem to have been introduced from Europe when Algiers (wax pole) was brought to this country, and German Black Wax (bush) was introduced about 1865.

Even after seed companies became interested in improvement work it was confined mostly to selections from existing stocks or to developing progenies from chance crossings. The seedsmen were seeking early varieties with less fiber in the pod walls and a reduction or elimination of strings as well as a certain smoothness of pod, and in some cases they considered an increase in pod size important. However, these seedsmen gave only incidental attention to offtypes appearing in their stocks, and progress was not very rapid.

The most successful of these early plant breeders was Calvin N. Keeney, of Le Roy, N. Y. Among his productions are Pencil Pod Black Wax, Brittle Wax, Rustless Golden Wax, Wardwell Wax, Burpee Stringless Green Pod, Surecrop Stringless Wax, Giant Stringless Green Pod, and one strain of Stringless Green Refugee. These varieties were all stringless and of very high culinary quality when compared with such varieties as Early Six Weeks and Mohawk, and they all became popular in spite of the fact that they were not quite so hardy as the older varieties. Brittle Wax has persisted as the most popular wax for canning, and Stringless Green Refugee is still the most satisfactory type for canning high-quality green beans. Pencil

[4] Crystal is the term used to describe a nearly colorless, rather translucent-appearing pod

Pod Wax is of very high quality, but the tendency for the pods to curve has kept it from being a popular garden or shipping bean, and the black seed has prevented it from attaining great popularity as a canner. At the time, however, Burpee Stringless Green Pod was sensationally successful and was grown in most home gardens as well as for canning and shipping. The great success of this one variety stimulated Keeney, as well as other breeders, to continue the development of new stringless varieties, while Burpee Stringless Green Pod remained very popular with home and market gardeners, and Giant Stringless Green Pod became the favorite for an early canning variety for packs of cut beans. Part of Keeney's varieties were introduced by the W. Atlee Burpee Co., part by himself. During the last few years the Keeney stocks have been consolidated with those of two other seed companies incidental to the formation of the Associated Seed Growers, Inc.

D. G. Burlingame, of Genesee County, N. Y., introduced Bountiful in 1898. Other early plant breeders were A. N. Jones, of Le Roy, N. Y.; W. H. Grenell, of Pierrepont Manor, N. Y.; and John Kramer, of Doylestown, Pa.

At the present time the most popular flat-podded, early green snap bean for shipping is Bountiful. There is some competition among early round pods, but Black Valentine (Henderson, 1897), New Stringless Green Pod (Associated Seed Growers, Inc., 1930, from Tendergreen, Henderson, 1922), Full Measure (Henderson, 1906), Burpee Stringless Green Pod, and Giant Stringless are the most popular. Red Valentine, a very old bean of uncertain origin, is still used to a small extent. In some sections Stringless Green Refugee (Keeney, 1908) and 1000:1 Refugee (a very old variety) are still used for late shipping beans. The former is also the most important late canning bean where a high quality pack is desired.

Among the wax beans, Hodson Wax (Harvey Seed Co., 1902) is the most popular late shipper. Webber Wax (1913), Sure Crop Wax (Keeney, 1911), and Davis White Wax (Davis, 1895) are popular early flat waxes for shipping. Brittle Wax (or Round Pod Kidney Wax), Improved Kidney Wax (Keeney, 1906), and Pencil Pod Wax (Keeney, 1900) are the most important of the wax beans for canning

Disease as a Factor in Bean Culture

The ravages of diseases early made it necessary for plant breeders to do additional work on the varieties introduced by Keeney and others after 1890. The three most important bean diseases in this country are caused by organisms that invade the seed tissues, remain dormant in them, start new outbreaks on the seedling plants, and cause losses later. These diseases are anthracnose, bacterial blight, and mosaic.

Anthracnose of beans results principally in dark, sunken spots on the pods, which make such beans unmarketable. In the case of dry shell beans the seed may be discolored. Anthracnose can be eliminated from any stock of seed beans by growing the stock in any of the seed-bean-producing areas west of the Mississippi River, since conditions in such areas are unfavorable for anthracnose development.

Bacterial blights cause water-soaked spots that later throw off a

gray or yellow exudate depending on the blight involved. Bacterial blights can be eliminated by growing in dry-land seed-bean areas, or in certain irrigated districts in Idaho and California.

Mosaic causes a green pattern in the leaf, and in severe cases the leaves may be distorted and the pods reduced in size. Mosaic spreads rapidly from one plant to another, and the symptoms often are not apparent. There is no place known where it is possible to eliminate mosaic from bean seeds by growing in a special environment.

In some cases organisms in the soil (frequently *Fusarium martii phaseoli* Burk.) cause severe injuries to the roots, which may reduce the stand or result in premature ripening, but such diseases are not seed-borne.

The relationship of seed-borne diseases to breeding work with various types of beans can perhaps best be explained by examples. Previous to the moving of the seed-bean industry to the West, anthracnose was the most serious bean disease. At the present time anthracnose is seldom seen in market-garden or canning varieties of beans unless the seed has been saved from an eastern-grown crop. On the other hand, anthracnose is quite common in field beans grown in the East, since most of the seed must necessarily be home-grown. New York grows large acreages of both snap and dry-shell beans, of which the latter are troubled yearly by anthracnose and the former only to a minor extent. New York State has had a vigorous breeding program in effect and has originated several strains resistant to various strains of *Colletotrichum lindemuthianum* (Sacc. and Magn.) Briosi and Cav., the organism that causes anthracnose. There has been no major program by any division of the Federal or State institutions to breed snap bean varieties resistant to anthracnose. Resistance to root-rotting organisms has been studied, but not much has been done to breed for resistance against them.

The Newer Bean Varieties

Productions by Private Breeders

In some cases improved strains not possessing any disease resistance have been introduced. Burpee Stringless Green Pod has been largely replaced by Landreth Stringless (about 1927), but the older name has been retained. The latter undoubtedly was of higher quality, but in some sections home gardeners object that the seed of the new strain does not develop quickly enough. On the other hand, quick seed development is a characteristic that shippers and most city consumers object to.

Giant Stringless, Full Measure, and Burpee Stringless have been losing popularity in competition with New Stringless Green Pod (Tendergreen). This new variety is more resistant to bacterial blights than the other three varieties and yields quite well under a diversity of conditions. It is said to come from an accidental cross of Stringless Green Refugee with Full Measure. It was introduced by Henderson in 1922 as Tendergreen, but was pure-lined, renamed, and introduced by the Associated Seed Growers, Inc., in 1930.

Asgrow Black Valentine Stringless was an introduction by the Associated Seed Growers, Inc., in 1930. It is said to come from a cross of Black Valentine with Pencil Pod Black Wax. It is interesting to

note in this connection, however, that some observers have found white and variegated seeds segregating from this variety. This bean is hardy and of very good quality—in contrast to the poor quality of Black Valentine—and is replacing the old Black Valentine rapidly in many shipping sections.

Stringless Green Refugee is very resistant to bacterial blights but extremely susceptible to common bean mosaic and to many other viruses infecting beans, as described by Zaumeyer and Wade (*95*) and Pierce (*51*). In some sections severe economic losses from common bean mosaic on this variety have occurred.

In spite of the specialized machinery developed for canning beans, snap bean varieties have remained essentially general-purpose varieties. However, in a few cases canning has tended to intensify the importance of certain varieties. Stringless Green Refugee has set a standard that canners have sought in an early variety. Stringless Green Refugee is a late, light-green-podded bean, stringless, essentially free from fiber in the side walls, fine-textured, and with small, straight, nearly round pods. It has been used mainly for packing whole, but any oversized pods are excellent for packing as cut beans. Some canners are not interested in the whole pack and can use a variety that will produce a large yield of beans of only moderate quality. In some sections Full Measure is the favorite. It is early, dark-green podded, stringless, essentially free from fiber in the side walls, medium to coarse in texture, with large pods. Where essentially the same qualities are desired but with lighter pods, Giant Stringless Green Pod is used. Flat beans are seldom canned. In the wax types a white-seeded early wax with the quality of Refugee Green is desired. The nearest approach is Brittle Wax, but canners object to the large eye, which can sometimes be seen in the processed beans.

Bean Breeding by Public Agencies

The United States Department of Agriculture began breeding work in 1922 to produce a Refugee type of bean resistant or tolerant [5] to mosaic. This work was started by Wilbur Brotherton in cooperation with the Wisconsin Agricultural Experiment Station and was later carried on by G. H. Rieman, W. J. Zaumeyer, and the writer. The first introduction was U. S. No. 1 (1933), an early mosaic-tolerant strain intermediate in type between Refugee and Full Measure. It has been favorably received in limited areas only and will probably remain of minor importance. The second Refugee type introduced by the Department came in 1935 and is designated U. S. No. 5. All reports on this bean have been very favorable. It is highly resistant to common bean mosaic and tolerant to bacterial blight, and the pods are not distinguishable from Refugee except that those of U. S. No. 5 are free from purple splashing caused by anthocyanin pigment. U. S. No. 1 is from the tenth generation of a cross of Refugee × Wells Red Kidney, and U. S. No. 5 is from a cross of U. S. No. 1 with a mosaic-resistant Refugee rogue. Previous to the introduction of U. S. No. 1 and U. S. No. 5, Rieman, in cooperation with the Wisconsin station,

[5] In this discussion the word "tolerant" is used to describe a variety that suffers no appreciable reduction in yield as a result of infection, although other disease symptoms may be clearly shown. "Resistant" refers to varieties that are apparently unaffected by the disease in any way.

had made fairly extensive tests of No. 536 Canning Wax, which did not prove to be commercially successful but which has since been used in breeding work for mosaic resistance and for quality of pods.

The Wisconsin station began breeding work with Refugee × Corbett Refugee (a rogue type), from which came Wisconsin Refugee and Idaho Refugee, both introduced in 1934. Wisconsin Refugee is about the same in season as Stringless Green Refugee. It is mosaic-resistant, but the type is not so well fixed as Idaho Refugee. Idaho Refugee is about a week earlier than Stringless Green Refugee. It is resistant to common bean mosaic and is being favorably received by the canning trade. The pods carry a slightly heavier purple splashing in both Wisconsin Refugee and Idaho Refugee than in the parent varieties, although there is a possibility of eliminating this by further selection. W. H. Pierce and J. C. Walker introduced these two strains.

The first bean to be bred especially for mosaic resistance was Robust. It is a strain of Michigan Pea bean (dry shell) and was introduced by F. A. Spragg, of the Michigan Agricultural Experiment Station, about 1913 from field selections.

W. H. Pierce and C. W. Hungerford, of the Idaho station, introduced Idaho No. 1 Mosaic Resistant Great Northern about 1930. It is a very hardy dry-shell bean obtained by selection from heterogeneous strains of Great Northern.

Further work on resistance to mosaic in snap beans is being carried on at the Michigan station by C. H. Mahoney and at the New York stations at Geneva and Ithaca.

One of the most interesting developments in connection with canning string beans is the sudden popularity of a strain of White Creaseback known in some places as Blue Lake. This is somewhat different from the ordinary strains of White Creaseback grown in home gardens. The pods are very long, dark-green in color, and round in cross section at a very early stage. Nearly all beans canned from this variety are put up in whole lengths in "asparagus" style. The popularity of this excellent dark bean may mean the beginning of a new era in American bean breeding, since the proponents of light-podded Refugee types can no longer consistently claim that high quality in a canning bean is associated only with light-green pods.

Bean rust is another problem that has required attention during the last few years. Kentucky Wonder and most strains of white-seeded Kentucky Wonder are susceptible to strains of rust. In 1934 L. L. Harter, of the Bureau of Plant Industry, United States Department of Agriculture, introduced U. S. No. 3 and U. S. No. 4 strains of white-seeded, rust-resistant Kentucky Wonder. These were pure-line selections from heterogeneous strains from Europe known as World Wonder and Phenomenon, respectively. U. S. No. 3 has been very favorably received. It is a very early pole bean, coming in bloom only a few days later than Full Measure. The pods are large, round, stringless at all stages, and of high quality. U. S. No. 4 is somewhat later than U. S. No. 3, and the pods are very long, flat, and stringless in early market stages. They represent an improved strain of what would ordinarily be considered white-seeded Kentucky Wonder. Further breeding work is under way involving crosses of

brown-seeded Kentucky Wonder with U. S. No. 3 and U. S. No. 4 and for resistance to other strains of rusts.

In connection with the bean-breeding program of the Department several green and wax canning, market-garden, and pole strains resistant to various diseases are now in the course of development. These are being bred and tested for the most part at Greeley, Colo., Charleston, S. C., and Beltsville, Md. Those now engaged in this work are W. J. Zaumeyer, L. L. Harter, and W. D. Moore in pathology, and the writer and C. F. Poole in genetics. For the last few years S. A. Wingard, of the Virginia Agricultural Experiment Station, has been developing strains of the Kentucky Wonder type suitable for growing in that State and resistant to rust. He has succeeded in establishing very satisfactory late strains that are not early enough for growing seasons in northern or north-central regions.

List of Varietal Introductions

Table 1 shows in a condensed form some of the outstanding bean varietal introductions of the last 20 years or so.

TABLE 1.—*Bean varietal introductions*

Variety or strain	Type	Special characteristics	Introduced by—
Robust	Dry shell (pea bean)	Resistant to common bean mosaic	F. A. Spragg, Michigan, 1913
Idaho No. 1 Great Northern	Dry shell	do	Pierce and Hungerford, Idaho, 1930
Geneva Red Kidney	do	Resistant to strains of anthracnose	Gloyer, 1928
York Red Kidney	do	do	Do.
Virginia Kentucky Wonder	Snap pole	Resistant to rust	Wingard, 1934
U. S. No. 3	do	do	Harter, 1934
U. S. No. 4	do	do	Do.
U. S. No. 1	Refugee	Tolerant to mosaic	Wade and Zaumeyer, U. S. Department of Agriculture, 1933
U. S. No. 5	do	Resistant to mosaic	Wade and Zaumeyer, U. S. Department of Agriculture, 1935
Idaho Refugee	do	do	Pierce and Walker, University of Idaho, 1934
Wisconsin Refugee	do	do	Walker and Pierce, University of Wisconsin, 1934
Corbett Refugee	Refugee rogue	do	Corbett, Sioux City, Iowa, 1931
No. 536	Canning wax	Resistant to mosaic, small pods	Rieman, 1928, U. S. Department of Agriculture and University of Wisconsin
Blue Lake	White Creaseback	High quality dark podded canner for whole length packs	Clear Lake Canneries (?), about 1930
Asgrow Black Valentine	Stringless Valentine	Stringless	Associated Seed Growers, 1930
Tendergreen	Full Measure	Tolerant to bacterial blights	Henderson, 1922
New Stringless Green Pod	do	do	Associated Seed Growers, 1930
Landreth Stringless Green Pod	Burpee Stringless	Refined pod	Landreth, about 1927
Stringless Red Valentine	Red Valentine	Stringless	Landreth, 1930

The development of new disease-resistant varieties of beans has done much to stimulate pure-line work among the seed companies, and many have greatly improved the standards of their basic seed stocks and of the stocks they deliver to canners and to market and

home gardeners. The complex nature of present-day breeding work makes it necessary for seed companies to employ plant breeders with an adequate knowledge of genetics and plant pathology.

LIMA BEANS

ALTHOUGH the botanical differences between lima beans (*Phaseolus lunatus* L.[6]) and common beans (*P. vulgaris*) are not great, it has so far not been possible to cross the two species. The most conspicuous difference is in the flower bracts. They are small, inconspicuous, lanceolate, and pointed in *P. lunatus* and large, conspicuous, and oval in *P. vulgaris*.

Lima beans cannot be grown as far north as common beans. In the South or in the Tropics if a set of blossoms is dropped because of drought or very hot weather, the long growing season still may give plenty of time for beans to be set later. Where the seasons are shorter, failure of the crop may result from the loss of the first blossoms. In California the long growing season makes it unnecessary for the first blossoms to develop into pods.

Limas became popular in the United States after 1824, when seed of the large type—as contrasted with the small-seeded civet or sieva type—was brought from Lima, Peru, by Capt. John Harris, of the United States Navy. It was found that the lima did especially well on the dry lands of southern California. The two limas now most extensively grown are both dwarf varieties, Henderson Bush and Fordhook. Henderson Bush was found along a roadside in Virginia by a Negro laborer about 1885. He sold it to T. W. Wood & Sons, of Richmond, who later sold the stock to Peter Henderson. It is a small erect bush type with very small, flat seeds. It can usually be counted on to produce a crop even under adverse conditions. Wood Prolific Bush, a later selection from Henderson Bush, is a slightly larger plant. U. S. No. 2 lima (1933) is a selection from Henderson Bush developed especially for uniform maturity of the pods on the individual vine. It is not distinct enough to constitute a variety, but under some conditions it may be from a few days to 2 weeks earlier than most strains of Henderson Bush. Henderson Bush and related types are grown to some extent in home gardens but are more generally used for commercial canning.

Canners have wished to combine the hardiness and yield of Henderson with the quality of Fordhook. In 1934 the McCrea Seed Co. introduced the McCrea lima, which is green-seeded when mature, of high quality, but late and not an especially good yielder in eastern canning districts. The green seed character is not apparent in either Henderson or Fordhook, so it is probable that the parentage is some large, green-seeded variety crossed with Henderson.

Fordhook, a large-seeded dwarf plant, was discovered in a field of Challenger pole limas by Henry Fish, of Santa Barbara, Calif., in 1903. Burpee introduced it in 1907. It is now the favorite market-garden variety. A small quantity is canned, but its popularity for canning has not been great because of its sensitiveness to adverse weather conditions.

---

[6]In ordinary botanical usage *Phaseolus lunatus* is the civet or sieva bean and *P. lunatus macrocarpus* Benth. the lima bean.

During the last several years the California Agricultural Experiment Station has introduced strains of a very hardy, high-yielding, small-seeded lima known as Hopi, selected by Mackie from limas grown by the Hopi Indians. Most of the Hopi and Henderson Bush grown in California are used as dry, edible beans.

A very noteworthy fact about lima bean breeding is that practically all varieties have arisen by selection and very few from controlled breeding work. Roy Magruder, of the Bureau of Plant Industry, is at the present time carrying on considerable breeding and genetic work involving seed-coat colors, seed sizes, and the breeding of various types for canning.

In the southern United States pole limas with either colored or white seeds are grown extensively in home gardens and to some extent for marketing under the name of butter beans. These are very hardy varieties and probably offer worth-while breeding material for crossing with nonhardy, high-quality varieties such as Fordhook.

GENETICS OF PEAS AND BEANS [7]

Peas

THE many stable forms of *Pisum sativum* early attracted the attention of those interested in theoretical scientific work as well as the attention of many breeders. It was with garden peas that Gregor Mendel in 1856 began his historic experiment, which laid the foundation for genetic science. His findings were made public in 1865 but attracted no attention until they were rediscovered by Correns, De Vries, and Tschermak independently in 1900.

Mendel worked with seven different factors: Yellow *v.* green cotyledons, smooth *v.* wrinkled seed coats, normal *v.* fasciated stems, tall *v.* dwarf growth habit, green *v.* yellow pods, parchmented *v.* nonparchmented pods, and the pleitropic factor for colored *v.* colorless seed coats, colored *v.* colorless leaf axils, and purple *v.* white flowers. A pleitropic factor is one that affects many different characters.

In spite of Mendel's success with the plant, peas have not proved to be ideal for genetic studies, and consequently most of the fundamental contributions since his time have been with organisms other than peas. There are probably several reasons for this: (1) Many single-factor differences frequently show wide divergences from a 3:1 ratio. (2) Linkage values may vary sharply from one cross to another. (3) Different classification of phenotypes gives rise to reports of more than 50 percent crossing over. (4) The number of independent factors and groups of factors appears to exceed the number of chromosomes. (5) Peas have proved to be rather difficult material for cytological studies.

Wellensiek (*85*) brought the available data up to date and has worked unceasingly to eliminate conflicts in designations of various factors. Matsuura (*39*) also reviewed and tabulated the literature dealing with *Pisum* genetics. The following lists of factors are taken largely from Wellensiek, with a few modifications by De Haan (*11*) and Winge (*92*). The number of genes listed is 68, but the known number may be in excess of this. In some cases it has been difficult

[7] This section is written primarily for students or others professionally interested in breeding or genetics.

to decide whether some ratios are the result of pleitropic effects of a single gene or the effect of several genes completely linked. Winge gives a table showing certain gene designations made by himself and 10 other authors, including De Winton (*93*), Wellensiek (*86, 87, 88, 89, 90*), Rasmusson (*55, 57, 58*), White (*91*), Lamprecht (*30*), Pellew and Sverdrup (*49*), Sverdrup (*70*), Nilsson (*42*), Kajanus (*21, 22*), H. and O. Tedin (*72, 73*), and De Haan (*11*).

Pisum Factors

A. Basic gene for anthocyanin color of the flower. It also influences indenting of seeds, seed-coat color, marbling of seed coat (except ghost marbling), leaf-axil color, violet and red pod colors.
A_1, crypto purple; A_2, purple dotted flowers; *a*, white.
Ar. Gene for reddening, salmon-pink flowers.
Ap. Apple blossom.
Am. Pinkish-white flowers.
B. Gene for bluing.
Bl, basic gene for wax or bloom; *bl*, waxless (emerald).
Bta, blunt apex; *bta*, acute apex. } Both recessives must be present in homozygous
Btb, blunt apex; *btb*, acute apex. } condition to produce acute.
Cp, curved pod; *cp*, straight.
Cr. Changes crimson to purple in presence of *A*. (Fedotov (*7*).)
Cv. Intensifies anthocyanin color in presence of *A* and *B*. (Fedotov (*7*).)
Cm. Cream flowers. (Fedotov (*7*).)
Em^1, Em^2, normal; em^1, em^2, emergences if both are present.
Ep' } Thickness of seed coat. (Kaznowski (*23*).)
Ep_1 }
Dw, *D*, *d*. Leaf axil ring double, single, absent. (Tedin and Tedin (*72*).)
F. Purple dotting of seed coat I. (Wellensiek.)
F_2. Purple dotting of seed coat II. (Winge.)
Fe, normal pods, fertile; *fe*, split pods, sterile as female. (Sverdrup (*70*).)
Fa, normal stem; *fa*, fasciated stem.
Fu, resistant to fusarium wilt; *fu*, susceptible.
Fl, gray spotting on leaves; *fl*, green leaves.
Fn, one or two flowers per peduncle; *fn*, three or more flowers per peduncle.
G, green cotyledon; *g*, yellow cotyledon. (Nilsson (*42*).)
Gp, green pod; *gp*, canary yellow pod.
H. With *A* gives orange seed coat.
I. Inhibits action of *G*, giving dominant yellow cotyledons.
If, intermediate flowering; *if*, early flowering.
J. In presence of *A*, causes dark-brown seed coat.
K, normal wings; *k*, keeled wings.
Kl. Inhibits coupling between *A* and *Gp*. (Hammarlund (*13*).)
L, L_1, L_2. Genes for wrinkling or dimpling of seed.
Le, Le_1, *le*. Long, very long, and short internodes.
La. Growth-inhibiting factor. (De Haan (*11*).)
Lb. Growth-inhibiting factor.
Lc. Growth-inhibiting factor.
Ld. Growth-inhibiting factor.

(*Le* dominates if *La* or *Lb* is present, but not if the two recessives, *la*, *lb*, are present. Either *Le*, *la*, *lb*, or *le*, *la*, *lb* is slender. 45:15:4 segregation of tall, short, slender in F_2.)

Lf. Retards flowering time caused by *If*; ineffective by itself.
Lo, Lo_1, Lo_2, Lo_3. Genes for seed length. (Kaznowski (*23*).)
M with *Z* gives "ghost marbling" of testa; with both *A* and *Z*, brown marbling.
M_1 to M_4. Genes for susceptibility to mildew. (Hammarlund (*13*).)
Mp. Rusty radicula. (Tedin and Tedin (*73*).)
N, thin pod wall; *n*, thick pod wall.
Nr, normal; *nr*, narrow rogues. (Pellew (*48*).)
O, *or*, *oy*. Green, lemon, gold pods, stems, and foliage.
Oh. Inhibits the expression of red, converts red to bright-brown seed coat.
P. Thin parchmented membrane in pod; *p*, no membrane.

P_1. Purple pod I } Both dominants necessary to make pod purple.
P_2. Purple pod II }
Pa, green pods; *pa*, pale pods.
Pe, normal pods; *pe*, pearl pods.
Pl, dark hilum; *pl*, light hilum.
Pt. Quick growth of pollen tube.
Q, aborted seed; *q*, normal seed. (Wellensiek and Keyser (*90*).)
R, round seed; *r*, wrinkled seed surface.

(*R* is hypostatic to *A*; *r* is epistatic to *A*. In conjunction with genes L_1 and L_2 of Hadfield and Calder (*12*), the following forms may be distinguished: Smooth, $l_1\ l_1\ l_2\ l_2\ RR$; dimpled, $L_1\ L_1\ L_2\ L_2\ RR$; wrinkled, $L_1\ L_1\ L_2\ L_2\ rr$; wrinkled, $l_1\ l_1\ L_2\ L_2\ rr$).

Re, normal leaves; *re*, reduced leaves.
S, seeds free in pod; *s*, seeds clinging together (chenille or brochette).
Sa_1, Sa_2, Sa_3. Genes for number of stomata. (Tavčar (*71*).)
Sg_1 to Sg_4. Genes for seed weight.
Sn_1, intermediate value for node number; sn_1, low value.
Sn_2, increases the value for node number caused by Sn_1; ineffective alone.
St, normal stipules; *st*, reduced stipules.
T, T_1, T_2. Genes for internode number.
Td, leaves dentate; *td*, leaves not dentate.
Tl, tentril leaves; *tl*, acacia (no tendrils).
U, violet seed coat.
Uni, Normal leaf; *uni*, unifoliate.
V, Strong membrane in pod; *v*, thin membrane.
Wb_1. Strengthening gene for wax.
Wb_2. Strengthening gene for wax.
W_2, green foliage; w_2, white variegated.
X. Stipule size. (Brotherton (*1*).)
Y. Stipule size.
Z, colored seed coat; *z*, uncolored seed coat.

As there are many factors influencing flower color, it is perhaps best to illustrate the genetic constitution of some of the many colors that occur. These are given from De Haan (*11*):

Purple	*A A Ar Ar B B Ap Ap Am Am*
Violet	*A A ar ar B B Ap Ap Am Am*
Rose	*A A Ar Ar b b Ap Ap Am Am*
Light purple	*A A ar ar b b Ap Ap Am Am*
Apple blossom	*A A Ar Ar B B ap ap Am Am*
Apple rose	*A A Ar Ar b b ap ap Am Am*
Apple violet	*A A ar ar B B ap ap Am Am*
Pinkish white	*A A Ar Ar B B Ap Ap am am*
White	*a a Ar Ar B B Ap Ap Am Am*

A cross of violet by apple rose results in a purple F_1 with a trihybrid ratio in F_2 of 27 purple : 9 violet : 9 apple blossom : 9 rose : 3 apple violet : 3 apple rose : 3 light purple : 1 expected to have an appearance between apple rose and light purple. According to the above scheme, all those having *aa* are white regardless of the rest of the genetic constitution. A certain white[8] × apple blossom results in an F_2 segregation of 9 purple : 3 apple blossom : 4 white. According to the designations of Fedotov (*7*), *Cm* can produce a cream flower and it is independent of the action of *A*.

In addition to flower color, the genes that have been listed have an influence on color of the leaf axil. Purple and apple-rose flowers are associated with purple axils; pinkish white, with dull-rose axils; violet and apple violet, with violet; rose and apple rose, with rose; and light purple, with light purple. *Dw* produces a two-ring effect in the axils, *D* a single ring, and *d* no ring.

[8] Only the white of the constitution *aaArArBBApApAmAm* will give the ratio cited when crossed with apple rose.

There is considerable variation in the amount of waxiness or bloom on peas. Waxiness is caused by a gene for wax *Bl*, and is intensified by the presence of either W^b_1 or W^b_2 or both.

Two genes (bt_a and bt_b) must be present in the homozygous condition for a pod to have an acute apex. Crosses between strains with blunt pods and those with sharp result in the F_2 either in a ratio of 15 blunt : 1 acute or of 3 : 1, depending on how many of the genes for bluntness were present in the blunt parent. There is at least one other factor influencing pod-apex shape.

The gene *fe* is responsible for a rather peculiar condition in which the developing pods split along the dorsal suture, resulting in the death of the developing seeds.

The fasciated or flattened stem condition is due to a recessive gene, *fa*. This flattened condition results in a terminal inflorescence that superficially resembles an umbel. Some flower stalks may produce from three to seven flowers, while others produce only one or two on the same plant.

Tallness and shortness in pea plants have long been of much interest, and it has been discovered that many factors are concerned with stem length. In some cases simple 3 : 1 ratios of tall to short are obtained in the F_2 generations from crosses of tall with short. In one such cross, however, De Haan (*11*) obtained an F_2 segregation of 45 tall : 15 short : 4 slender. Two recessive genes must be present to produce a slender plant. Gene *Le* is epistatic to *La* or *Lb* but hypostatic to *la* or *lb*. Genes *lc* and *ld* result in a slightly larger short plant designated "short 2." One of the factors for slender is identical with *lc* or *ld*, but it has not yet been determined which.

The edible-podded condition (no membrane) is determined by the recessive gene *p* in the homozygous condition. The factor *V* results in a very strong membrane when acting in conjunction with *P*.

Pt is a theoretical gene for quick growth of the pollen tube. Its presence has never been determined by actual ratios.

Round seeds are dominant to wrinkled, and segregation is by individual seeds. Several genes influence the condition known as indenting or dimpling, and segregation is by plant. A three-factor explanation has recently been given (*12*) of the conditions designated smooth, dimpled, and wrinkled, respectively.

Seed weight is influenced by several factors, the exact number of which has never been determined. Violet flower is sometimes associated with abnormal hilum, which results in low seed weights on plants having violet flowers. Many other factors also probably influence seed weights.

The Gradus rogue (rabbit ear) character (*1*) is a rather unique condition in which very rapid mutation of the recessive gene *x* for normal Gradus type to the dominant *X* (rogue) occurs when these genes are associated together in a cross. While other factors involved in a cross may be segregating as expected, no plants of normal type may be recovered in F_2 or subsequent generations.

Seed-coat colors are also affected by the gene *A* for anthocyanin. Factors *Ar* and *B* have an effect on seed-coat color parallel with their

effects on flower color, but *Am* and *Ap* have no effect on seed coat. The effects of *Pl*, *M*, *F*, *Oh*, *Z*, and *Mp* on flower color are known.

Disease Resistance

Hammarlund (*13*) reported that immunity of peas to powdery mildew was due to the presence of four genes, M_1, M_2, M_3, and M_4. The varieties commonly grown in the United States are all susceptible to powdery mildew, but artificial control methods have been effective in preventing damage by this organism. Neither genetic nor breeding investigations of powdery mildew resistance have been undertaken in this country.

Wade (*82*) reported that resistance to fusarium wilt of peas was due to a single dominant gene, *Fu*. This was slightly linked with *Le*. Extensive breeding work has been carried out by many workers, and

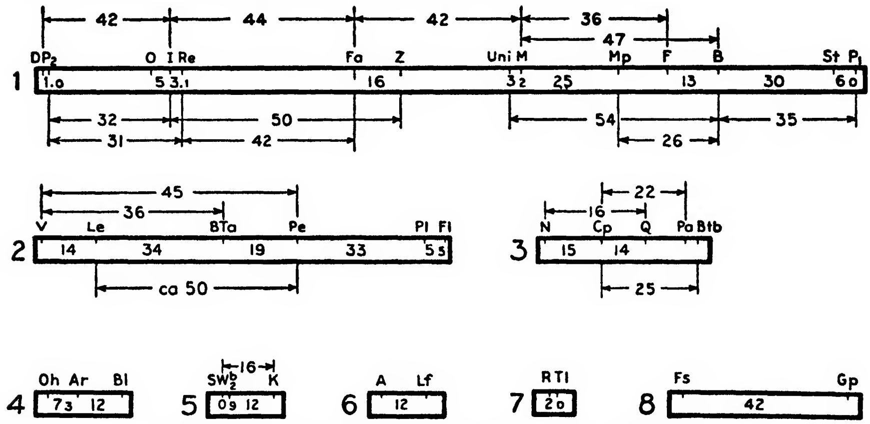

Figure 1.—**Linkage groups in *Pisum*. (After Winge.)**

at the present time all the canning varieties are available in wilt-resistant forms.

Zaumeyer and Wade (*96*) have shown that different varieties of peas show differential reactions to various types of legume mosaics. The presence of many diseases, frequently epidemic in nature, indicates that in the future much work will be done in connection with the inheritance and breeding of disease-resistant strains of peas.

Various reports have shown that many varieties of peas possess some tolerance to the attacks of various root-rotting organisms, but the genetic bases of these reactions have not been determined.

Linkage and Cytology

The contribution of Winge (*92*) on linkage in *Pisum* has greatly clarified the linkage situation. He describes eight linkage groups, which are here redrawn (fig. 1) from his publication.

It is believed that further research will eventually reduce the number of linkage groups to seven, to correspond with the number of pairs of chromosomes known to be present in *Pisum sativum*.

Ring formation (*9*) seems to be the most satisfactory explanation of many of the variable linkage results obtained by Rasmusson, Wellen-

siek, Tedin and Tedin, and other workers. Although Rasmusson (*56*) shows the genetic nature of some linkage intensities, the number of factors involved in the segregation of these intensities is not known. Håkansson (*10*) reports a semisterile condition in association with chromosomal exchange. Sutton (*69*) reports an instance of half disjunction in a case involving four chromosomes.

Beans

The literature on bean (*Phaseolus vulgaris*) genetics and breeding is very extensive. Kooiman (*24*) presents a very thorough review of the subject and does much to clarify conflicts in terminology. Doornkaat-Koolman (*4*) had previously reviewed the literature, especially that dealing with disease resistance. Matsuura (*39*) also presents a summary. Much of the material in this paper is drawn from reviews by these authors, with stress on literature published since 1929.

Inheritance in beans has been investigated for a long time, but there are still many divergent results that need further studies for adequate interpretation. This is especially true with regard to flower colors and their relationship to seed and pod colors.

Shaw (*66*) and Shaw and Norton (*67*) present extensive observations on flower colors, which indicate that at least two factors must interact for the production of pigment in flowers. According to their observations, most varieties with pigmented seeds, with the exception of Red Valentine, have colored flowers. However, many other exceptions to the observations of these authors are now known.

Johannsen (*19*) obtained a dihybrid ratio in progeny from a cross of a white-flowered brown-seeded bean variety with a violet-flowered black-seeded one.

Tjebbes and Kooiman (*76*) explain the results of a spontaneous cross of violet × lilac-flowered, in which dark violet, light violet, lilac, and white flowers appeared in association with red and blue pods and various seed colors on the basis of three genes. *R* causes red pod striping whether or not the ground factor *A* for seed-coat color is present. When *A* is present the flowers are lilac; the seed coat is red, due to *R*. *Bl* changes these colors to bluish tints. Heterozygous *Bl bl* results in light violet. They assumed a total of seven genes for flower color.

Kooiman (*24*) suggested an eight-factor explanation of the various seed-coat colors encountered.

Sirks (*68*) presented a factorial explanation of various seed-coat colors and summarized the literature up to that date.

Lamprecht (*25*, *26*, *27*, *28*, *29*, *31*, *32*, *33*, *34*, *35*) has presented a very satisfactory explanation of most of the seed-coat colors encountered in beans. He assumes eight pairs of genes and the following interactions among them:

P. Basic color factor, in itself producing no color.
C with *P* gives sulphur white; *Cc*, mottled.
J. Pale ecru in seed coat, also in hilum.
G with *PCJB* gives mineral brown; with *PCJV* gives maroon brown; with *PCJBV* gives black; with *Ca* gives caruncle streak.
B with *PCJG* gives mineral brown; when heterozygous with *PCJVv* gives dark dull green; when homozygous with *PCJV* or *PCJVG* gives black.
V with *PCJG* gives maroon brown; when heterozygous with *PCJBb* gives dark dull green; when homozygous with *PCJB* or *PCJBG* gives black.

R. Red.
Ca. Caruncle streak; shows only in presence of G.
PCJ. Chamois color.
PCJG. Blister (yellowish brown).
PCJgB. Golden bronze yellow.
PCJgbV. Violet purple.
PCJGB. Mineral brown.
PCJGV. Maroon brown.

(Chamois, *PCJ*, in the presence *G* and *B* gives mineral brown; *G* and *V* give maroon brown; *B* and *V*, both heterozygous, produce dark dull green; while *B* and *V*, either homozygous or in the presence of *G*, produce black.)

PCJBbVv. Dark, dull green.
PCJBVG. Black.

Micropyle streak is recessive and will not show in the presence of either or both inhibiting factors *Mi* and *Mia;* furthermore, *J* is necessary for its expression even when the inhibitors are absent.

Later, Lamprecht (*33*) has shown that factors *J* and *R* are inherited independently, and that in addition to the *Cc* inconstant marbling there is also *Rr* inconstant marbling.

Schreiber (*64, 65*) explains his results on a somewhat different basis. Genes M_1 and M_2 must both be present to produce a constant marbling effect. *B* is a factor for light brown; *C* is an intensifier. *D* is for dark green, effective only in the presence of the basic color factor *A* or *P*. *L* inhibits partial spotting caused by Shaw and Norton's "*T*". Miyake, Imai, and Tabuchi (*41*) found all seedcoat colors hypostatic to black.

Tschermak (*78*) suggested two genes for eye pattern:

(1) $z_1z_1Z_2Z_2$. Seeds having half or more of the testa pigmented with sharp limits.
(2) $z_1z_1Z_1z_2$. Seeds having half or less pigmented, without sharp limits.
(3) $z_1z_1z_2z_2$. Pigment confined to a small hilum spot.

Sax (*60*) found in his crosses of two types of Yellow Eye beans that the heterozygous condition resulted in a pigmented area exceeding twice that of the parents. Only a single gene was involved.

Currence (*3*) found two distinct types of bean pod stringiness, one due to two dominant complementary genes, the other to an incompletely dominant gene for stringlessness with an inhibiting factor. Joosten (*20*) distinguished 10 classes of stringiness. Prakken (*53*) found 15 stringless to 1 stringy in an F_2 generation.

Tschermak (*78*) observed 3:1 and 13:3 ratios in F_2 for nonconstricted versus constricted pod. Lamprecht (*26*) interpreted his results on the basis of four factors.

Emerson (*5*), Lock (*36*), Doornkaat-Koolman (*4*), and Tschermak (*79*) found green pods dominant over yellow (wax) with a 3:1 ratio in F_2. Currence (*3*) found two factors to determine the difference between these characters.

Tschermak (*79*) found a single factor difference between round versus flat, with round dominant. Wóycicki (*94*) and Currence (*3*) found several factors involved.

Miyake, Imai, and Tabuchi (*41*) have studied the inheritance of color of stem. Two types of green crossed together gave a red F_1, followed by a segregation of 9 red : 7 green in F_2. Pink × green gave 9 red : 3 pink : 4 green.

Emerson (*5, 6*) shows that there are three factors involved in bean height: (1) Determinate versus indeterminate growth; (2) number of internodes (in pole beans this depends largely on environmental conditions); (3) internode length.

Norton (*45*) interprets his results by means of three factors governing height:

A–a. Indeterminate *v.* determinate.
L–l. Tall *v.* short.
T–t. Twining *v.* nontwining.
ALT. Pole beans.
ALt. Runner beans, nontwining pole.
Alt. Shoots from main axis short; some few early, twining shoots.
aLT and *aLt.* Spreading forms with long branches.
alT and *alt.* Erect, bush.

Three-to-one segregations of tall to short have been observed by McRostie (*37*), Tjebbes and Kooiman (*76*), and Doornkaat-Koolman (*4*).

Table 2 gives some bean characters not considered above.

TABLE 2.—*Bean characters*

Contrasted characters	F_2 segregation	Author
Blunt *v.* sharp leaf apex	3:1	Tschermak (*78*).
Broad *v.* narrow leaf	Complex	Emerson (*5*), Wóycicki (*94*).
Long *v.* short internode	do.	Tschermak (*78*), Wóycicki (*94*).
Nonparchmented *v.* parchmented pod	3:1	Emerson (*5*), Tschermak (*78*), Wellensiek (*84*).
Threshable *v.* difficult to thresh	3:1	Tjebbes and Kooiman (*76*).
Yellow *v.* green cotyledon	3:1	Tschermak (*78*).
Yellow *v.* chamois seed	3:1	Nilsson (*43*).
Straight *v.* curved pods	3:1 and 2 modifying factors.	Lamprecht (*26*).
Round *v.* elliptical pods	3:1 and bifactorial	Do.
Normal *v.* unifoliate leaves	3:1	Lamprecht (*35*).
Partially colored seeds	4 or 5 genes	Lamprecht (*31*).
Unlimited *v.* limited growth of axil	3:1	Lamprecht (*34*).
Unbranched *v.* branched inflorescence	3:1	Do.

Disease Resistance

Several strains are known of the organism *Colletotrichum lindemuthianum*, causing bean anthracnose. Burkholder (*2*) and McRostie (*37, 38*) have studied the inheritance of resistance. Where one strain of fungus was concerned, a ratio of 3 resistant to 1 susceptible was obtained; two strains resulted in a 9:7 ratio. Further work is being done on this problem at Cornell University and in the United States Department of Agriculture.

Schreiber (*64*) indicates that there are three independent factors for resistance corresponding to three anthracnose strains.

McRostie (*38*) in crosses involving Robust Pea bean × Flat Marrow observed the F_1 showing a partial dominance of susceptibility. F_2 indicated at least a two-factor difference. Pierce (*52*) and Parker (*47*) have studied the inheritance of resistance to common bean mosaic, using different bean varieties. Parker concluded that since reciprocal crosses gave different results, at least part of the material for resistance was carried in the plant outside the chromosomes. Pierce did not attempt to show a genetic interpretation.

It is interesting to note in connection with the maternal inheritance suggested above that Hoffman (*16*) found that modifications persisted

for six generations after he had treated navy beans with chloral hydrate. These modifications were transmitted only by the cytoplasm of the egg cells and not through the chromatin. It is also of interest to note that Parker (*46*) has found an undoubted case of maternal inheritance of leaf variegation.

Zaumeyer and Wade (*95*) and Pierce (*51*) have indicated that more than one strain of bean mosaic or of legume viruses transmissable to beans are in existence and that bean varieties differ in their reactions to them. Genetic studies of varieties resistant to the viruses are now in progress in the Department.

Rands and Brotherton (*54*) tested the resistance of many varieties and strains of American and foreign beans to several diseases, including at least three strains of the anthracnose organism, bacterial blight, bacterial wilt, and mosaic, and found differential reactions in some cases.

Fromme and Wingard (*8*) made a report on resistance and susceptibility of various bean varieties to rust. There is much material available for genetic and breeding studies in connection with this disease.

McRostic (*38*) made some observations on the inheritance of resistance to dry root rot of beans, caused by *Fusarium martii phaseoli*, but he did not attempt to give a factorial explanation of his results.

Crossing Technique and Interspecific Hybridization

Beans are somewhat difficult to cross, since the curled and brittle style of the flower is easily broken during the process of opening the keel. If the atmosphere is kept near the saturation point for a few days after artificial pollination has been effected, the chances for success are much better than in only a moderately moist atmosphere. The time required to make crosses has prevented genetic studies in *Phaseolus* involving backcrosses.

Many attempts have been made to secure interspecific hybrids within *Phaseolus*, mostly without success except for that involving *P. vulgaris* and *P. multiflorus*. In such hybrids there is usually a great deal of sterility and variability in results, even in the F_1. Mendel (*40*), Doornkaat-Koolman (*4*), Tschermak (*78*), and Tjebbes (*74*) have made studies involving this interspecific cross. At the present time the United States Regional Vegetable Breeding Laboratory, near Charleston, S. C., is testing a variety from Mexico that arose from the cross of *P. vulgaris* with *P. multiflorus*.

Linkage and Cytology

Weinstein (*83*) has shown that *Phaseolus vulgaris* and all other species of *Phaseolus* have 11 pairs of chromosomes.

Tjebbes (*75*) recognizes two linkage groups. Linkage in the *B–A–R–S* group is very close, showing a cross-over value of less than 1 percent between *B* and *S*. *S* is a factor for striping and the other three factors influence the seed-coat color. Genes *C* and *G* are in another group with a cross-over value of about 35 percent.

Several factors give pleitropic effects or the effects are in reality due to more than one factor. However, in such cases it usually requires extensive work to establish the nature of the gene or the closeness of the linkage involved.

Sax (*60, 61, 62, 63*) attempted to analyze quantitative characters by studying their linkage relations to qualitative genes. He demonstrated at least five cases of linkage.

Lima Beans

Only a very limited amount of genetic work has been done with the lima bean (*Phaseolus lunatus* L.). Rhind (*59*) reports genetic studies involving three factors, which he designates as—

R. Rose color seed coat.
P. Intensifies rose to purple seed coat.
S. Speckled seed coat.

Roy Magruder, of the Bureau of Plant Industry, is carrying on genetic studies with *Phaseolus lunatus*.

IMPROVEMENT IN THE LEAFY CRUCIFEROUS VEGETABLES

ROY MAGRUDER, Olericulturist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

ACCORDING to most botanists, cabbage, cauliflower, broccoli, green-sprouting broccoli, brussels sprouts, kale, collards, and kohlrabi are very closely related, being horticultural forms of the species *Brassica oleracea* L. Kohlrabi is assigned by some botanists to *B. caulorapa* (DC.) Pasq. Wild cabbage (*B. oleracea*), illustrated in figure 1, from which all these forms or varieties are supposed to have arisen, is still found growing wild along coastal regions of Europe and northern Africa. Its use by man as food antedates written history, and it is believed to have been in rather common use for more than 4,000 years.

Figure 1.—A wild cabbage plant.

Just when or where the various forms or varieties of cabbage first appeared or were developed it is difficult to say with any degree of certainty because of the lack of written records. Kale and collards (var. *viridis* L.) are probably the oldest type, and the present wrinkled or ruffled type was mentioned by Theophrastus in 350 B. C. and described and illustrated by Dodonaeus in 1559. Red cabbage or kale was also known to Theophrastus, and Pliny describes heading cabbage (var. *capitata* L.) and includes in his list of types a savoyed or blistered-leaf type which is thought to be the ancestor of our present savoy cabbages. The name savoy indicates that much of the early developmental work occurred in the locality of Savoy in southeastern France. Cauliflower and broccoli (var. *botrytis* L.) are believed to be more recent additions to our types and to have been developed from the green-sprouting broccoli. Kohlrabi (*Brassica oleracea* var. *gongylodes* L., or, if considered a species, *B. caulorapa*) probably was brought north to the low coastal countries of Europe by way of Prague and Vienna. The two most important varieties of today are White Vienna and Purple Vienna. Brussels sprouts (var. *gemmifera* DC.)

were not mentioned by the early writers prior to 1759, but by 1793 this vegetable was an article of international commerce, and its origin is generally ascribed to Belgium.

THE PART PLAYED BY SEEDSMEN IN THE DEVELOPMENT OF CABBAGE

Varieties of vegetables as we speak of them today in our seed catalogs hardly existed before the last of the eighteenth century either in the United States or in Europe. This date corresponds with the rapid rise of seed growing as a business venture in Europe, and no doubt the competition between seedsmen for something new to offer their customers was, then as now, the incentive that led to the rapid introduction of varieties.

The early named varieties were groups of plants with a few common characteristics but many variations. The more observant, careful, and critical growers were always looking for improvements, and when plants were found that seemed superior, these were selected for seed propagation. By continued selection of superior or distinctive types suitable to the particular locality in which the grower lived, many local strains or horticultural varieties—as distinct from botanical varieties—were developed. The local seed seller disposed of any surplus the grower might have, and, as the industry developed, an opportunity was afforded for the general distribution and trial of many varieties over a wide range of conditions. If the variety performed well in its new location, it soon attained major importance. If it was unsuitable in general yet possessed some special merit, it probably was the starting point for a new variety, which was developed as the result of continued selection for the especial point of merit. Thus the early development of all our crops was the work of observant and critical growers who through superior skill in selection and seed growing gradually became the local sources of superior seed. The early seedsmen were merchants, not growers or breeders of seed.

A SINGLE *piece of publicly supported plant breeding saved the cabbage-growing industry in many sections of the country and brought an enormous return on the cost. This was the work begun in Wisconsin in 1910 by L. R. Jones, and continued through the cooperation of J. C. Walker and his associates of the United States Department of Agriculture, to develop varieties resistant to the devastating cabbage yellows or fusarium wilt. As a result, there are now yellows-resistant varieties of all the major types of cabbage demanded by the market. Today other diseases are receiving the attention of breeders, as well as the problem of adaptation of varieties to definite regions and the development of types superior in eating quality and in ability to hold up well in storage.*

The types or varieties of cabbage were developed mainly by the people of the Netherlands, Denmark, Germany, France, and England. When brought to this country by the early settlers, they were not always suited to our climate, which generally was hotter and drier than the climate of the north European countries. The uncertainty of supply and the cost of imported seed forced the isolated grower to attempt to produce seed for himself. Starting with imported seed, he proceeded to select the individual plants that best suited his needs and grow seed from them. If he wanted something earlier maturing, later maturing, with less outer leaves, more rounded head shape, smaller size, more heat-resistance, or what not, he selected toward that goal and in many instances was successful.

The enterprising mail-order seed dealer was largely responsible for the location and introduction to the public of many of these locally developed strains, sometimes with the growers' name affixed but many times with a name selected by the introducer. The high prices paid for these types stimulated seed growers in their effort to find new and superior varieties or strains. Some of the growers soon found they could make more money by growing seed than from the market crop and devoted their energies to seed production. Most of the early cabbage-seed growers were located on Long Island, N. Y., because of the favorable growing conditions there.

At the beginning of the nineteenth century most of the cabbage grown on Long Island belonged to three types: Early York, an early maturing variety with elliptical heads; Flat Dutch, a large midseason variety with flat heads; and Red Dutch, a late, hard, round-headed variety. The Flat Dutch type was more productive and in greater demand on the market than the other two types, and most of the American varieties or strains introduced during the nineteenth century were selections from the Flat Dutch type. An objective of major importance to all growers of cabbage was that every plant should produce a marketable head, and this characteristic is emphasized in the names of some of such varieties as All Head and Surehead. Selections were also made for earlier and later maturing strains of the Flat Dutch type in order to extend the marketing season over a longer period. Some of these selections for difference in maturity resulted in differences in head shape and size and in a rather wide range in type when compared with the parent variety. The early growers were also interested in securing cabbages resistant to disease, and the Houser and Bugner varieties are the results of the efforts of two men along this line. As the seed business became more highly competitive and the growers more critical, the matter of attaining uniformity of type became an object of considerable attention and effort. At the present time there are available very uniform stocks of varieties that cover the entire range of season of maturity and are satisfactory in head size and shape.

A list of the cabbage varieties of known American origin with the year of introduction and other information is given in table 1.

It is also of interest to note which of our present-day important varieties are foreign introductions. In the list of what may be regarded as the nine principal American varieties of cabbage we find Early Jersey Wakefield, Copenhagen Market, Early Winningstadt,

Glory of Enkhuizen, Late Flat Dutch, and Danish Ballhead to be the names of orginal importations, although the present strains of the first and of the last two varieties show a decided improvement in uniformity of type, which may be attributed in part at least to the efforts of American seedsmen. Other varieties of lesser importance that are known to be importations by American seedsmen are Golden Acre, Resistant Detroit, Early York, San Francisco Market, Volga or Early Stonehead, and almost all of the red and savoy varieties.

TABLE 1.—*Cabbage varieties of known American origin*

Variety name	Producer	How produced	Parental variety	Introducer	Year introduced
All Head Early	Mr. Strong, Long Island, N. Y.	Selection	Flat Dutch	W. Atlee Burpee & Co.	1891.
All Seasons (The Vandergaw).	Mr. Vandergaw, Long Island, N. Y.	do	do	James J. H. Gregory.	1886.

BREEDING WORK BY PUBLIC AGENCIES

THE severe losses caused in the cabbage-growing sections of Wisconsin by cabbage "yellows" or fusarium wilt led Jones (*6*),[1] of the Wisconsin Agricultural Experiment Station, to start selection work in 1910 toward the development of yellows-resistant varieties. The work was continued through the cooperation of J. C. Walker, of the United States Department of Agriculture, and his associates (*3, 7, 8, 29, 30,*

[1] Italic numbers in parentheses refer to Literature Cited, p. 298.

31, 32, 33) to the point where we now have yellows-resistant varieties of all the major types. A good example of a yellows-resistant cabbage is illustrated in figure 2. (See the appendix for the list of 10 varieties and years of introduction.) This one piece of publicly supported plant improvement work has saved the cabbage-growing industry in many sections of the country and resulted in an enormous return on the cost.

Workers at the Iowa Agricultural Experiment Station (*14*) have also produced an early yellows-resistant variety of cabbage, Iacope, by selection on disease-infested soil from the Copenhagen Market variety,

Figure 2.—Comparison of yellows-resistant and yellows-susceptible breeding lines of cabbage on heavily infected land. Rows *a* and *c*, resistant progenies; row *b*, susceptible.

and introduced it in 1922. It has since been very largely replaced by earlier and more uniform strains from the Wisconsin work. In 1926 C. E. Myers, of the Pennsylvania station, released a strain of Ballhead called Penn State Ballhead, which was produced by pedigree selection for uniformity and solidity of head and for large yields under Pennsylvania conditions. The work of J. C. Miller, at the Louisiana station, has resulted in the production of a strain called Louisiana Copenhagen, which is earlier, slightly smaller, and shorter-cored and has harder heads under Louisiana conditions than commercial strains of Copenhagen Market, from which it was produced by inbreeding and selection. As a result of the inbreeding, hydridization, and selection work of C. H. Myers and W. I. Fisher at the New York (Cornell) station, nine new varieties or improved strains of cabbage have been introduced.

(See table 4 of the appendix for list and special characters of each.) Several other State experiment stations and the United States Department of Agriculture have cabbage-improvement programs under way from which no introductions have yet been forthcoming (see table 6 of the appendix).

Present Trend in Cabbage Improvement

The major emphasis in cabbage breeding is now upon the development of strains that are resistant to diseases other than yellows, strains that are particularly well adapted to a definite locality, or strains with superior eating or storage quality. There is need for an early-maturing, round-headed, winter-hardy, nonbolting variety of cabbage that can supplant Jersey Wakefield for wintering-over in the South Atlantic coastal region. Our best early round-headed varieties are usually either killed by the cold in this region or produce seedstalks when planted in the fall. Work on this problem is well under way, and it is hoped that within a few years a strain or variety will be available that will combine the hardiness and nonbolting of Jersey or Charleston Wakefield with the more productive and more desirable head characteristics of Golden Acre or Copenhagen Market. Except for sauerkraut manufacture, there is a decided preference for heads of small to medium size, very hard, with mild or sweet flavor and crisp or succulent texture. The development of strains especially adapted to cultural conditions in the large production centers in various sections of the country is another problem on which cabbage breeders are working.

Usual Breeding Method for Biennial Brassicas

In improving cabbage or other Brassicas by selection, commercial seedsmen commonly select several plants possessing the desired characteristics and store them over winter either in cold storage or by burying them in the field under alternate layers of soil and straw or other coarse litter. As soon as the ground can be prepared in the spring, the plants are transplanted to their permanent location. In the case of cabbage, vertical cuts are made on four sides of the head to enable the seedstalk to push through. The mature seed from each plant is saved separately, and the plants that result from it are planted in a separate row the next year. At harvest time only the plants having the desirable characteristics from the most uniformly desirable row (which of course comes from a single head) are selected for storage and seed production the following year. The breeding block and the fields for increasing seed should be at least one-fourth mile distant from any other varieties of Brassicas in order to prevent crossing.

Selfing (applying the pollen of the flower to its own stigma and preventing pollination by other plants) is the most rapid method of securing uniformity in type, but because of the reduction in vigor usually caused by inbreeding the Brassicas, the large proportion of self-sterility present in these plants, and the special equipment and large amount of hand labor required, this method has not come into widespread use by commercial breeders. Various methods of surmounting some of these difficulties are discussed in the section on Developments in Breeding Technique.

American Improvements in Other Brassicas

No plant-improvement work with kohlrabi has been or is being done by any of the American seed growers or the State or Federal research institutions. Cauliflower, likewise, has not been worked with successfully, because of the difficulties attendant upon seed production in this country.

Broccoli seed, however, can be grown successfully in California, and the Ferry-Morse Seed Co. has developed a number of strains that differ in their ability to make marketable heads at different periods through the winter and early spring months. The names November, Christmas, February, March Early, March Late, and April indicate the seasons at which the heads mature most successfully. Green sprouting broccoli, a rather recently revived introduction from Italy, has been much improved in uniformity of type and productiveness by several seed growers.[2] By proper manipulation it can be easily grown as an annual to produce seed the first year.

Long Island Improved, a half-dwarf strain of brussels sprouts selected and improved by early Long Island growers and seedsmen, is the only important variety of this vegetable listed in many American seed catalogs. Very recently the Gill Bros. Seed Co. of Portland, Oreg., has introduced a dark-green strain called Oregon Special, and a medium-green taller strain called Half Moon Bay. The latter probably developed among the growers in the Half Moon Bay section of California.

Improvement work on kale by seedsmen has been limited to fixing the type or selecting more uniform strains. In 1936 the Virginia Truck Experiment Station released a strain of kale and named it V. T. E. S. Scotch. It has blue-green, heavily curled leaves and is more cold-resistant and more uniform than commercial stocks of this Dwarf Blue Curled Scotch type.

Louisiana Sweet is the name of a uniform, shorter petioled, solid green-colored strain of collards introduced in 1934 by the Louisiana Agricultural Experiment Station as the result of several years' inbreeding and selection work in the Georgia collard variety.

Developments in Breeding Technique

As a result of numerous experiments by workers with cabbage and related crops, improvements in technique have been made that greatly facilitate breeding and improvement work. In the work for early-maturing yellows-resistant varieties of cabbage great difficulty was experienced in keeping the plants over winter in storage because of decay and rots that developed during the long storage period. It was discovered that cutting the roots or pulling them loose on one side of the plant and then on the other side at a later date would delay the maturity of the plant until late in the fall. With greenhouse space available, it was possible to transplant the selected plants into large pots, which could then be moved into the greenhouse before freez-

[2] The only consistent difference between broccoli and cauliflower is that broccoli will produce marketable curds during the cold winter weather in the Pacific Coast States, whereas cauliflower requires the warmer weather of the spring season. So the "cauliflower" that easterners get in the winter from the west coast is grown from broccoli seed. "Green sprouting broccoli" does not form a dense 'head" or curd, as is the case with white-heading broccoli or cauliflower, because the floral branches elongate and are not blanched by protecting leaves.

ing weather. When grown at low temperatures until the seedstalk started to elongate, these plants would bloom during early spring and produce seed for sowing in May. This made it possible to treat the usually biennial or perennial cabbage as an annual and greatly speeded up the work. It was also more convenient and easier to do crossing and self-pollination in the greenhouse than in the field. It did not conflict with other field work in the late spring or early summer. Figure 3 illustrates the use of a greenhouse for pollination work.

Figure 3.—Artificial control of cross- and self-pollination of cabbage in the greenhouse. The use of the greenhouse in winter makes it possible to obtain a new generation each year instead of every 2 years.

It was also determined that testing for resistance to yellows could be done as well in the greenhouse under the proper temperature conditions (68° to 77.5° F.) in disease-infested soil as in the field. The plants that proved to be resistant could then be grown to maturity in the greenhouse, and those selected for propagation would produce seed during the winter and early spring without any period in storage, where the plants might be lost through disease or decay.

In breeding for shortness of stem or core, compactness of head, and superior eating quality, it is necessary to remove the head for examination and testing. When cabbages were grown in Louisiana as a fall crop, it was found that the axillary sprouts would develop after the head was cut, and, if the weather was cold enough during December, January, and February, the plants would produce good crops of seed in time to sow for the next fall crop. If the plants were to be

moved into a greenhouse the transplanting was delayed until the lateral sprouts had made a good compact growth.

In some seasons the field-grown plants failed to produce seedstalks and instead produced small heads from the lateral sprouts. Difficulty was sometimes experienced in getting all of the plants to make seedstalks when the material was grown in the greenhouse during the winter. A series of experiments at Cornell University showed that a rest period of approximately 2 months' duration at about 40° F. was required for the subsequent formation of seedstalks. This period could be spent in the fall either in storage or in the greenhouse, and if the temperature was then raised to 70° and maintained there, ripe seed could be produced for sowing in May. Plants that were not given the cold treatment when grown in greenhouses at a temperature of 60° to 70° produced no seedstalks, indicating that a period of low temperature is necessary for the subsequent formation of seedstalks. Increasing the length of day by the use of 5 hours' electric illumination at the end of the daylight period did not cause the appearance of seedstalks in plants grown continuously at the warm temperature (60° to 70°) or hasten their appearance in the cold-treated plants.

In genetic work the use of pure-breeding or homozygous strains is advantageous. Various degrees of self-sterility have been encountered when inbreeding members of the cabbage family to produce such strains. Numerous lines more or less self-fertile have been isolated, but the importance of starting with large numbers of individuals should be emphasized in any program that calls for inbreeding. Experiments to determine the proper time to pollinate cabbage have shown that better seed production results when pollinations are made several days before or several days after the flower first opens. Lines or families that produce practically no seed when pollinated with their own pollen after the flowers open may produce good crops of seed when pollinated from 1 to 5 days before the flower normally opens. Hand-pollination in the bud stage is effected by separating the surrounding sepals with the points of a pair of tweezers and applying the pollen from a mature anther to the exposed stigma. It is not necessary to remove the sepals, and in fact they may be helpful in preventing drying out of the pistils.

It has been well established that not only are there various degrees of self-sterility or self-incompatibility but also there are various degrees of cross-incompatibility among plants of related or unrelated origin. Careful hand pollinations are necessary to determine the exact fertility relations among strains or lines, but the facts when established are useful in working out a breeding program or in the production of hybrid seed on a commercial scale, as pointed out by Pearson (*22*). By planting in alternate rows strains that are self-incompatible but cross-fertile, hybrid seed will result through the action of insects in carrying the pollen from one strain to the other. Bud pollination of a few flower clusters of each strain results in enough seed to perpetuate the strains for later crops. Bees have been found to be very effective agents in the cross transfer of pollen, and by enclosing the individuals or groups of plants under cheesecloth cages the bees may be used in working out the problem of obtaining desirable crosses between different strains or increasing the seed of a number of desirable crosses for preliminary commercial tests (*23*).

When incompatibilities are encountered, it may be possible to continue the improvement work by following a method of alternating selfings with mass increase. The first step is the production by bud pollination of as large progenies as possible of the desirable individuals. Most of the commercially important characters are quantitative in inheritance and large numbers of plants are necessary to produce enough individuals of the desired type. A number of desirable individuals of the same type are selected from the best line or lines and each lot or group is grown in an isolated location, where the plants are open-pollinated. The seed from all the plants of each lot or group are lumped together and sown. Plants of the desired type are selected from the best lots of this planting and bud-pollinated. The seed from each bud-pollinated plant is saved separately and selections for massing are made only from the best lines. In a few years it will be possible to eliminate all but one best line, which, when uniform for the desired characters, may be increased for commercial use.

Propagation of new plants from the axillary buds or sprouts of cabbage has been followed by commercial growers of cabbage when it was desirable to increase the variety or individual as rapidly as possible. Only recently, however, has it been demonstrated (*5*) that vegetative propagation from the head or curd of heading broccoli was possible. The most satisfactory material was from pieces of the curd with scale leaves attached. When placed in a propagating house maintained at 55° F. during the night and with low humidity and plenty of ventilation, these developed roots in 20 days. and in 40 days elongation of the floral axis had taken place.

By transplanting to the field in late spring the shortened stems of plants that had produced a crop of seed in the greenhouse, Miller (*16*) was able to force the development of new heads from lateral buds during the summer and by subsequent cold treatment to produce another crop of seed the following spring. By thus manipulating the environment in which the plants were grown he was able to maintain the cabbage plant as a perennial and yet produce a crop of seed annually.

Pearson (*22*) at the California Experiment Station worked out a rapid and ingenious method for determining the solidity of the cabbage head by determining the apparent specific gravity or density.

CYTOLOGY AND GENETICS OF LEAFY TYPES OF BRASSICA[3]

Cytological investigations of a number of workers have shown that the wild cabbage found along the seacoasts of Europe, various varieties of heading cabbage, kohlrabi, kale, collards, cauliflower, heading broccoli, green sprouting broccoli, and brussels sprouts all have nine pairs of chromosomes ($n=9$). No significant differences have been reported in size or form among the chromosome sets of any of these forms of botanical or horticultural varieties. Hybrids among any of these forms are usually highly fertile, although sterility may sometimes occur, as is pointed out in the section on genetic studies and in the article on root crops (turnips and rutabagas). Botanical varieties of

[3] This section is written primarily for students or others professionally interested in genetics or breeding

Brassica oleracea have been successfully crossed with radish (*Raphanus sativus* L.) (see the article on root crops), and rarely with other species of *Brassica* having different chromosome numbers, the resulting hybrids usually being entirely or highly self-sterile.

The wide diversity of form and function in *Brassica oleracea* would seem to make it an ideal species for genetic analysis, and except for several circumstances, our knowledge might be much more extensive than it is today. Much of the early work cannot be considered dependable because open-pollinated varieties were used. The presence of self-sterility has discouraged many workers from attempting to secure inbred lines with which critical work could be undertaken. Many of the horticultural or botanical varieties require 2 years' time to complete the life cycle and relatively large areas of land. Provision must also be made to prevent cross-pollination by insects. Transference of pollen from anther to pistil must be done by hand or by insects enclosed in the isolation chamber, and extensive use of the backcross is almost prohibitive because of the large amount of hand labor required to get a sufficiently large number of seeds. In spite of these difficulties a number of studies have been made on the inheritance of various characters in the cabbage family. The more important contributions are briefly reviewed below under sectional headings indicating the plant character studied.

In view of the wide range of materials used it is not surprising that the workers report different results with what appear to be the same characters. It is obvious that critical genetic work on the Brassicas has only begun.

Leaf Color

Kristofferson (*12, pt. I*) reports on the inheritance of leaf color in various *Brassica oleracea* botanical and horticultural varieties. He tentatively assumes the interaction of five factors, each with the following effect: *A* produces no color alone, but with *B* produces the dark red violet midrib; *B* causes the light-red midrib; *C* under favorable conditions is able to produce a very faint pink color but with *A* produces the dark-violet midribs of kale; *D* causes the general dark-red color of red cabbage; *E* is concerned with the distribution of the dark red violet color.

The factorial composition of the material with which he worked and its phenotypic appearance with regard to leaf color is given as follows:

Red cabbage, *AbcDe*, dark red violet midrib and blade.
Kale, *Abcde*, green midrib and blade.
Cabbage, *aBCdE*, light-red midrib and green blade.
Brussels sprouts, *aBCdE*, light-red midrib and green blade.
Broccoli, *abCdE*, green midrib and blade.

The evidence presented in support of this hypothesis is far from conclusive, and the author himself in 1927 (*12, pt. II*) concludes: "For a firm establishing of the factorial basis of the total dark red violet color it may be necessary to grow the F_3 generation." He also states in this later paper that the factor *D* "shows any effect only when both factors for violet, *A* and *C*, are present," which is evidently at variance with the scheme proposed in the first paper.

Other workers (*1, 25, 28*) have found a single factor difference between red (purple) and green foliage. Pease (*26*) and Molden-

hawer (*17*) conclude that two complementary factors are concerned in the inheritance of color in a purple kohlrabi × Green Savoy hybrid, for in the F_2 they obtained 9 purples : 7 greens.

C. H. Myers, of Cornell University, has isolated a type designated as magenta that is more nearly red than the so-called red cabbage, which he calls purple. Sun red is also a new foliage color name for a genetic type that shows reddish purple on the stem and midribs and on the edges of leaves on mature plants exposed to sunlight. Genes controlling purple and magenta, magenta and sun color, and sun color and green are reported to be allelomorphs respectively. Crosses between magenta and sun color gave a purple F_1, and 9 purple : 3 sun color : 4 magenta in the F_2. Working with related families, Magruder (*13*) obtained an F_2 of 9 purple : 3 magenta : 3 sun color : 1 green from a cross between a magenta and sun color, indicating the interaction of two independent genes in the production of the purple type studied. There was only a single factor difference between sun color and green and between magenta and green. Kwan (*11*) used different families of the Cornell material and in a cross of purple × sun red the F_2 approximated 15 purple : 1 sun red, suggesting duplicate factors responsible for the purple. The same purple crossed with green gave an F_2 of 9 purple : 3 sun red : 4 green, indicating that this purple was not the same type as that used by Magruder.

In a review of the inheritance of leaf color it is obvious that a standard nomenclature should be used or detailed descriptions given in terms of one of the recognized color dictionaries. Free exchange of genetic color types among investigators would also facilitate a complete analysis of color.

Other Leaf Characteristics

In a cross between wide blade (cabbage) × narrow blade (kohlrabi), Pease (*25*) found the F_1 to approach more nearly the broad type, and in the F_2 the narrow type constituted about one-fourth of the total. Kristofferson (*12*), however, in a cross between broad (cabbage) and narrow (kale) found that the F_1 resembled kale and most of the F_2 plants had more or less intermediate type leaves, but parental types were also obtained.

A type of leaf in which outgrowths of a leafy nature called "asparagodes" occur along the midrib and larger veins at right angles to the plane of the blade was found by Pease (*26*) to be dominant to the normal leaf type and due to a single factor. Detjen (*4*) reports a similar character in his material but believes its expression is due to multiple factors.

The curliness of kale was found to depend on the action of several genes. The F_1 of a cabbage × kale cross is intermediate in curliness, and the F_2 shows continuous variation between the parental types. Malinowski (*14*) assumed three polymeric genes, Allgayer (*1*) four, and Pease (*26*) and Detjen (*4*) an indeterminate number. Kristofferson (*12*), however, reports a red cabbage × kale cross in which the F_2 was relatively uniform and in which neither parental type appeared. Kwan (*11*) crossed wrinkled (savoyed) and smooth-leaved cabbages and concluded that the wrinkled condition is due to the complementary action of two factors. There was no evidence of linkage of either of the factors for wrinkled leaves with either of the complementary factors for purple foliage color.

Contrasting entire with lyrate leaf shape, Pease (*25*) found entire to be due to a single dominant gene.

Petioled type of leaf as contrasted with sessile was found to be due to a single dominant gene by Pease (*25*); but Allgayer (*1*) postulated the action of three genes after his study of a cross between red cabbage and kale. Detjen (*4*) found the F_1 of a cross between winged (sessile) and petiolate to be fully winged, which is the reverse of the condition described by Pease (*25*). He concludes that in his material "clean petiolate head leaves are governed by a recessive factor which may be one of a multiple series." Environment has a marked effect on the expression of this character and makes a study of it very difficult.

Counts of the number of leaves below the mature head showed that in the F_1 the number of leaves was generally that of the parent with the smaller number, but Pearson (*24*) concludes that "according to the evidence, the number of leaves is probably governed by modifying factors."

Height of Plant

Tallness of plants is dominant to dwarfness and is due to a single gene according to Pease (*25*), Malinowski (*14*), and Allgayer (*1*). Kristofferson (*12, pt. II*) found continuous variation in plant height between the parental types in the F_2 and concludes that numerous genes are involved. Detjen (*4*) also concludes that length of stem is dependent upon multiple factors for its expression. Kwan (*11*) obtained plants taller than his tall parent and shorter than the short parent in the F_2 generation, with the F_1 showing marked increase in height over the tallest parent. He says:

> The data suggest that the inheritance of plant height can probably be explained on the assumption that a series of dominant independent cumulative factors favorable for growth are concerned, and that each parent strain carried only part of these favorable factors.

No estimate of the number of factors was made, but the normal distribution of the F_2 population indicated that the factors concerned were of equal value. There was no evidence of linkage between plant height or plant color or foliage surface.

Head Characteristics

Most investigators have found the F_1 from crosses between cabbage and any nonheading *oleracea* (except *gemmifera*) to show a slight heading tendency, and the F_2 to exhibit continuous variation with recovery of both parental types, true heads being in the minority. Malinowski (*14*) and Allgayer (*1*) consider that heading depends on the action of three pairs of genes. Pease (*25*) attributes it to duplicate genes, while Detjen (*4*), working with related headless and heading types of cabbage, found heading to be "fully dominant among related plants, or else the heading factor in headless strains is prevented by one or more factors from clearly manifesting itself."

In crosses between inbred lines Pearson (*24*) concludes that "head shape, in general, is controlled by many factors, of no definite dominance." Crosses between long- and flat-headed strains of Copenhagen Market showed an intermediate shape. "There is some slight evidence that certain head factors are complementary to each other, since one group of crosses produced flatter heads than the parents."

Detjen (*4*) concludes that "head form is not governed by single factors but may depend on a combination of several to many factors."

In crosses between inbred lines Pearson (*24*) found some of the F_1 lines to exceed either parent in weight; in others the F_1 equaled the larger parent; and in crosses between closely related lines no increase in size resulted in the F_1 generation. Detjen (*4*) records several crosses in which plant size of the F_1 showed size equal to or greater than the larger parent.

Crossing brussels sprouts (which have axillary heads but no terminal head) with cabbage (the reverse of brussels sprouts) results in an F_1 that closely resembles the brussels sprouts parent but has a head at the top. In the F_2 there is continuous variation in the tightness of the axillary buds, with a tendency for most of the plants to have loose heads or buds. Kristofferson (*12*) believes the formation of axillary heads is governed by many factors that are independent of factors for the formation of the terminal head.

The formation of axillary shoots is due to a single factor and is recessive to nonformation, according to Allgayer (*1*).

In crosses among inbred strains differing in the relative length of the core, Pearson (*24*) found from his F_1 results that "no dominance is shown in the inheritance of penetration of the core into the head." Hybrids between short- and long-core types have been intermediate in length.

Season of Maturity

By utilizing inbred lines and F_1 hybrids among them, Pearson (*18*) concluded that the season of maturity is—

> dependent in part upon genetic factors, and that hybridization with resulting increase in vigor is not necessarily accompanied by an earlier time of maturity; likewise that environmental differences do not affect all strains in the same way, and that for a definite test, replications together with check rows are very necessary.

Detjen (*4*) says that "heading is found to be governed by a multiple factor for season, which fact explains the many seasonal strains." Rasmusson (*27*) noted an early maturity of the F_1 from crosses among varieties of the same season of maturity. In crosses among early- and late-maturing varieties he notes the F_1 as being only a little later than the earliest parent.

Swollen Stem; Bolting; Corolla Color

The swollen stem or bulb of kohlrabi is incompletely dominant to unswollen stems (as in cabbage) in the F_1, and in the F_2 there is continuous gradation between the parental forms indicating the presence of several genes for bulbing in the kohlrabi. Pease (*26*) presents the clearest data in support of three factors, B_1, B_2, and B_3, of which the first two are major factors and the third a modifying factor. In homozygous condition B_1 and B_2 result in bulb, and when either or both are in heterozygous condition the presence of B_3 converts the stalk into "semibulb" condition. From crosses among related lines of cabbage differing in their stem diameter, Detjen (*4*) concludes that stem diameter is hereditary and dependent on many factors.

Certain varieties are known as "bolters" because when sown in the fall they produce seedstalks instead of heads the following spring. Sutton (*28*) crossed a bolting and a nonbolting strain of cabbage and found the F_1 to be nonbolting and the F_2 to contain approximately 3 nonbolting : 1 bolting. Detjen (*4*), working with strains of cabbage from the Volga variety, found bolting to behave as a monogenic dominant over nonbolting or biennial habit, although he recognizes that bolting is influenced by other genes for time of maturity and heading.

White corolla color was found by Pearson (*19*) and Kakizaki (*10*) to be due to a single gene and dominant to the yellow corolla color.

Self- and Cross-Incompatibility or Sterility

According to Kakizaki (*9*), self- and cross-incompatibility in cabbage is caused by the slow rate of growth of the pollen tubes. In incompatible pollinations the slow growth is due to the presence of a substance that inhibits the growth of pollen tubes through the stylar tissue and in compatible pollinations the normal growth rate of the pollen tubes is due either to the absence of the inhibiting substance or the presence of an accelerating substance able to prevent the inhibiting action. The inhibiting substance is produced most abundantly when the pistil is in full vigor, and its production declines with the decline of the vigor of the pistil. The pseudofertility of bud pollination of incompatible matings is due mainly to insufficient inhibiting action, owing to immaturity of the style, and to the lower time interval for pollen-tube growth, as well as to the shorter distance to be traversed. Kakizaki's results are explained by the hypothesis that two contradictory allelomorphic series of genes are concerned. S_1, S_2, and S_3 constitute the inhibiting series and T_1 and T_2 the accelerating series. The S series is epistatic to the T, but "T in double dose is more active than S in simple dose." In order to explain different degrees of fertility it is assumed that the allelomorphs function in different intensities or that one or more factors of minor value are concerned. When selfed, some self-incompatible plants breed true, while others segregate into 1 self-compatible : 3 self-incompatible. Self-compatible always segregates into 1 self-compatible : 1 self-incompatible. Pearson's (*21*) results "in most respects agree with those of Kakizaki", and Detjen (*4*) likewise agrees that—

> incompatibility in the common cabbage is governed in the main by a series of multiple allelomorphs which result in the manifestation of very distinct types. There are, however, other factors outside of such series that may affect the compatibility of plants such as was observed in the complete reversal of the Zinnia Rosette strain from practically complete self- and cross-incompatibility to practically full self-compatibility. Environmental factors such as temperature also may affect seed setting and temporarily mask the genetical factors.

Resistance to Yellows

Walker (*32*) has clearly demonstrated that resistance to yellows (*Fusarium conglutinans* Wr.) is a monogenic dominant to susceptibility to the disease in most of the yellows-resistant varieties developed by him and his coworkers. Anderson (*2*), one of his associates, has shown that the resistance of Wisconsin Hollander is genetically complex, as it cannot be permanently fixed and is influenced by environmental conditions. When grown at 22° to 24° C. all plants of Wisconsin

138904°—37——20

Hollander are susceptible, while resistant types in which the resistance is due to the single dominant factor are fully resistant at these temperatures.

LINKAGE

The results of Pease's work (*25, 26*) indicate the existence of three of the possible nine linkage groups. In the first group are found the genes (or one of a multiple series) for (1) petiolate leaves, (2) one of the genes for head formation, (3) entire leaves, (4) wide leaves, (5) possibly one factor for crinkling of the leaf, (6) bulbing of stem, and (7) red (purple) foliage color. A second group contains (1) a second gene for head formation, (2) a gene for tall plant habit, and (3) probably one of the genes for leaf crinkling.

"Asparagodes" malformation of the leaf thus far has not been linked with either of the above groups.

Malinowski (*14*) and Pease (*25*) report complete correlation between the degree of head formation and curliness in the F_2 of a cabbage$\times$curly kale cross. Malinowski inferred that the heading was due to three pairs of genes, *ABC*, and that curliness is produced by three other pairs of genes, *XYZ*, with complete linkage between *A* and *x*, *B* and *y*, and *C* and *z*.

IMPROVING THE ROOT VEGETABLES

C. F. Poole, Cytologist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

Did the ancient civilizations arise in the regions where our common cultivated food plants originated and were naturally abundant? Or did man take food plants with him, so that the early centers of civilization only seem to be the centers of origin of the plants? This must remain an interesting subject of speculation, but few students doubt that civilization was dependent on the natural locations of the plants. At any rate, the regions that are now believed to be the natural centers of origin of the root vegetables (*40, 41*),[1] which were used as food long before recorded history, include practically all of the centers of the oldest civilizations. The present belief is that in the Old World there were six of these, with five of which we are here concerned, and in the New World two major and two minor centers, all of which produced valuable root vegetables:

(1) Central and western China—radish, turnip, taro (dasheen).
(2) India (except northwestern India)—taro.
(3) Middle Asia (Punjab and Kashmir)—turnip, rutabaga, radish, carrot.
(4) Near Asia—turnip (secondary center), beet, carrot.
(5) The Mediterranean—turnip, rutabaga, beet, parsnip, salsify.
(6) Ethiopia—no root vegetables.
(7) Mexico—sweetpotato.
(8) South America (major)—taro, potato.
(8a) Chile—potato.
(8b) Brazil-Paraguay—cassava.

The theory is that the place where a plant exhibits the greatest diversity of subspecies and varieties in its natural state must have been a center of origin of that plant.

The value of the root vegetables is due to the fact that they are biennials, storing food[2] in their roots during the first season to support the second season's growth. Among the cultivated root vegetables, man has been able to select fairly true breeding varieties, which differ from one another chiefly by the shorter or longer time intervals they require to reach maturity. In some regions an ordinarily biennial crop may be changed into an annual, or vice versa, by planting seed early enough so that the plant will bolt, or produce seed the first season, instead of enlarging its root for winter dormancy. In all the biennial crop plants there are numerous varieties reputed to be nonbolters, meaning that they take longer to mature than varieties not so designated. Genetically, the hereditary factors governing time to

[1] Italic numbers in parentheses refer to Literature Cited, p. 322.
[2] The stored food is most frequently in the form of starch and starchlike substances, important elements in the human diet.

maturity in most of our root crops must be numerous, and the terms annual and biennial are not strictly accurate because of the many gradations.

From the beginnings of agriculture almost to the present there has been no conscious effort to improve the root vegetables beyond selecting seed from particular plants whose roots struck the grower's fancy. Within the last century, however, there has been more or less continuous activity in improving plants by crossing diverse types and selecting new combinations of characters. With the development of Mendelism into the science of genetics it became apparent that crossbreeding was essential for rapid plant improvement, and furthermore that an intelligent hybridization technique required a knowledge of the breeding behavior of chosen parents In the case of cross-pollinated species, like the root crops, the breeding behavior or the real genetic make-up of the parents can be determined only by inbreeding to produce lines homozygous or "pure" for their own characteristics. This must be combined with the keeping of pedigree records. With all our root vegetables, however, the inbreeding program is sometimes exceedingly difficult, for two reasons to be discussed later.

IMPROVEMENT OF ROOT CRUCIFERS

THE old method of plant improvement is inadequate for our present needs. The numerous kinds of insects and fungus diseases attacking cruciferous root vegetables (turnip, rutabaga, radish) necessitate the production of new resistant or immune strains by the more recent methods, including inbreeding, crossing, and the use of wild ancestral forms in the search for superior qualities. When established commercial varieties are planted in regions where insects are most numerous or in soils or regions where the fungus diseases are most

THE *old method of plant improvement is inadequate for our present needs. The numerous kinds of insects and fungus diseases attacking such root vegetables as the turnip, rutabaga, and radish necessitate the production of new resistant or immune strains by the more recent methods, including inbreeding, crossing, and the use of wild ancestral forms in the search for superior qualities. In all the cruciferous root vegetables the deliberate attempt to breed for resistance to diseases or to produce special kinds of vegetables has been neglected thus far. But if practically nothing has been done in the way of improvement by modern breeding methods, there has been enough genetic research and working out of adequate techniques to lay the foundations on which to build a practical program.*

damaging, seed can be produced only by plants that are entirely immune or partially resistant to attack. If no natural immunity or resistance is found in commercial stocks, it can usually be found by the introduction of wild ancestral forms of these cultivated vegetables from their original home sites. In all the cruciferous root vegetables the deliberate attempt to breed for resistance to diseases or to produce special kinds of vegetables has been neglected thus far. But if practically nothing has been done in the way of improvement by modern breeding methods, there has been some genetic research and the working out of adequate technique, as will be brought out later. The ground work has been laid on which to build a practical program.

Breeding of Turnip and Rutabaga

The name turnip is commonly applied to vegetables that, in their present cultivated condition, are botanically classified in three separate species of the genus *Brassica*. The point should be stressed, however, that cultivated forms of plants represent complexes of characters that make them quite different from their wild prototypes. This has resulted from many generations of selection for characters, usually Mendelian recessives, which accumulate in combinations not found in nature.

In the United States the name turnip is applied to plants of the species *Brassica rapa* L.,[3] a species wherein all plants examined cytologically have 10 pairs of chromosomes. In Europe the name turnip is frequently applied to the group of plants that we call rutabagas (bagas, or sometimes Swedish turnips), known as *B. napus* var. *sativa rapifera* Hort. by some botanists, and as *B. campestris* var. *napobrassica* DC in Bailey's Standard Cyclopedia of Horticulture. The rutabaga has shown 18 pairs of chromosomes in two cytological examinations by Karpechenko and Frandsen and 19 pairs in one examination by Nagai and Sasaoka (*29*). It is important to know the number of pairs of chromosomes in a species, or at least in the particular stocks used for parents, because crosses between species having unlike numbers of pairs are less easily made and are less regular in breeding and fertility than crosses between those with the same number. A discussion of chromosome numbers in the genus *Brassica* is given by Pearson (*30*).

In general, the chief distinguishing characteristics of the turnip are that the roots are mostly disklike or decidedly flattened, though ranging from spherical to elongated conical; the leaves are hairy, usually not fleshy, and greatly varied in outline; and the plants reach maturity in from 42 to 80 days. The commonly grown varieties show a wide variation in time to maturity, as the following indicates:

	Days
White Milan	42
Snow Ball	43
Purple Top Strap Leaved	46
Purple Top White Globe	55–60
Golden Ball	60–65
Cowhorn	70
Yellow Aberdeen	70–80
White Norfolk	76

[3] Frandsen and Winge (*8*), however, in reporting on the cytology and genetics of the progeny from a cross between the turnip and rutabaga, call the turnip parent *B. campestris* var. *sativa rapifera*, and Vavilov (*41*) calls the turnip *B. campestris* var. *rapifera* Metzg.

The principal turnip varieties reach maturity more quickly than the principal varieties of rutabagas. Since the turnip and the rutabaga will readily cross, however, it is probable that these turnips reaching market size around 65 to 80 days after planting are the results of natural turnip-rutabaga crosses.

The chief characteristics of the rutabaga, or Swedish turnip, as it is sometimes known, are a root that is tankard-shaped or elongated, although sometimes globular; a fleshier and larger leaf than the turnip; leaves not hairy; and a longer period of time (from 85 to 90 days) required for reaching the best pulling stage. Among the most commonly available yellow-fleshed rutabaga varieties on the American market are American Purple Top, Early Neckless, and Bangholm. Two white-fleshed rutabaga varieties are Sweet Russian and White Rock.

Disease Resistance in the Turnip

Although no deliberate attempt has been made to breed disease-resistant varieties of turnips or rutabagas, a new variety of turnip known as The Bruce, that is highly resistant to the slime mold disease called clubroot, has recently been introduced in Great Britain, New Zealand, and Australia. Clubroot attacks many species of the crucifer family, including cabbage, radish, mustard, cauliflower, sweet alyssum, and many others. It is now present in every country where the common cruciferous vegetables are cultivated. The Bruce is supposed to be a natural hybrid between the turnip and the rutabaga, and it first appeared in Scotland about 1820, some 40 years after the time that clubroot first appeared in Great Britain in 1780. The seed of The Bruce was carefully guarded in Aberdeenshire, and as it was disseminated throughout the district it was known to local farmers under different names, until within the last 10 years all agreed on its present name. The variety is still in a highly heterozygous state; that is, it appears in a great range of shapes, colors, firmness of flesh, size of seed, and degrees of resistance to clubroot. Tradition says that the rutabaga parent had a purple top and white flesh and that the turnip parent had a green top and yellow flesh, but these differences are not enough to account for the persistence of a high degree of variability.

Evidently much of the variability is due to the fact that the two parents had different chromosome numbers—10 pairs in the turnip and 18 pairs in the rutabaga—and the present descendants are still segregating for differences in number of chromosomes. From a plant-breeding standpoint it is of interest to note that in tests conducted recently in Scotland (7) the stocks of The Bruce that are less resistant to clubroot proved to be the stocks that have grown on soils less heavily infected with the slime mold.

Many different forms of clubroot exist, and the studies show that different varieties of turnips or rutabagas may be resistant to one or several strains of the slime mold but susceptible to others. Evidently The Bruce combines the largest number of resistance factors, and some strains are therefore nearly immune to this disease.

In addition to the fact that some strains have practical immunity to clubroot, whether grown on limed or unlimed soil, the best strains of the variety also have a higher percentage of dry matter than other turnip varieties included in the same test.

Breeding of the Radish

The radish, *Raphanus sativus* L., is a native of China and India, and its cultivation was practiced in ancient Egyptian and Grecian gardens. Because of its low-food value it has always been more popular as a home-garden vegetable than as a truck crop. It is a good subject for genetic study, since it exhibits a wide range of varietal forms in shape, size, and color of roots, time required from planting to market maturity, and keeping quality. A number of species crosses involving the radish have proved of considerable value to the plant breeder as well as the cytogeneticist. The condition known as self-incompatibility, which means that plants cannot normally be fertilized by their own pollen, is widespread in commercial varieties, but this can be removed by the selection of self-fertile inbred lines.

The leading radish varieties are most frequently classified according to the seasons in which they are grown. Spring varieties, such as French Breakfast, White Tipped, and Scarlet Turnip, are quick-maturing and require from 24 to 30 days' average time to marketing. The leading summer varieties—White Icicle, White Strasburg, and Giant Strasburg—are larger and better keepers and require from about 30 to 42 days to market maturity. The winter varieties, such as Long Black Spanish, Round Black Spanish, White Chinese Winter, and Mammoth White, have the largest roots, require 50 to 60 days to reach market maturity, and keep for several months when well stored.

Our varieties were all developed by crude selection without the aid of artificial cross-breeding to produce special types. A considerable number of genetic analyses have been made with radish, however, and with these as a beginning it is quite likely that plant breeders will take advantage of cross-pollination to produce new forms better adapted for special purposes or localities.

Of great interest from the standpoint of plant breeding is the fact that the radish has been successfully used in generic crosses with the cabbage. According to reliable records, the first successful cross between the radish and the cabbage was made in 1826 by Sageret, a gifted French plant breeder. This wide cross between two genera has subsequently been duplicated by several other investigators, with especially interesting results in the two instances to be reported later.

BREEDING OF THE GARDEN BEET

Although the origin center of the beet, *Beta vulgaris* L., is well known to be western Asia and the Mediterranean region, our commercial varieties have resulted from mass selections, based on the appearance and quality of roots at the end of the first season, to meet western European tastes. The beet flower is largely wind-pollinated, and cross-fertilization can be effected in areas separated a dozen or more miles. The practice of gathering seed for commercial stocks of beets from open-pollinated plants is responsible for the maintenance of self-incompatibility in beet varieties. Recently, however, seedsmen and geneticists are using specially produced inbred lines to obtain improved stocks free from rogues and from self-incompatibility (fig. 1).

The pollination technique in the beet, described later, demands unusual care, because even the protection given by airtight bags will

be undone upon removal to effect controlled cross-pollination unless the breeding plot is removed from possible contamination Self-pollination for inbreeding requires isolation, either geographic or

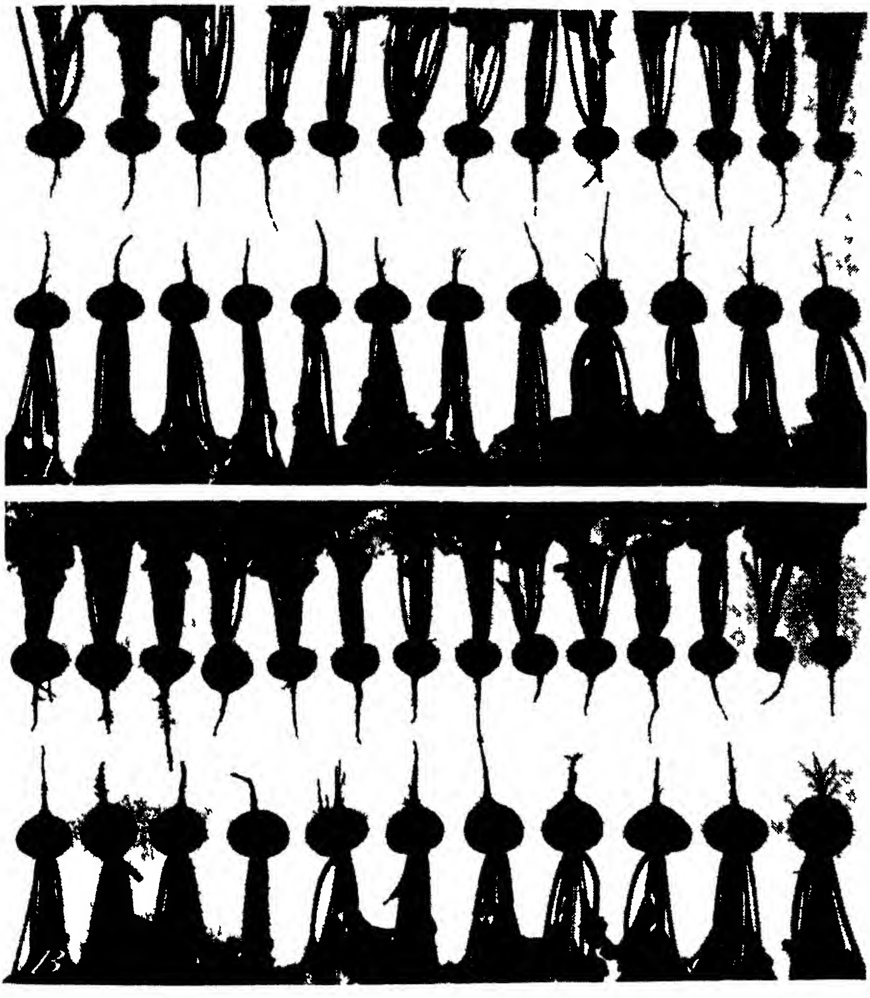

Figure 1 —Effect of inbreeding or line breeding in developing high uniformity and market quality in beets. A, Stock of Ohio Canner developed by selection and line breeding from Detroit Dark Red, B, good average commercial stock of Detroit Dark Red Note superior uniformity in shape of beets in A as compared with those in B

physical, and it is necessary to start with strains that are already self-fertile in some degree

The leading beet varieties differ considerably in length of growing season, and the time to market maturity of the most popular varieties extends from about 57 to 78 days. Beets may be grown so as to be available on our markets all year round by storing the slower-maturing

ones, like Long Smooth Blood, under relatively humid conditions. The leading varieties are all of the red beet type, and they include Asgrow Wonder, Crosby Egyptian, Ohio Canner, Detroit Dark Red, and Long Smooth Blood.

New beet species from Anatolia, recently imported into Germany and examined cytologically by Scheibe (*1*, *33*), have chromosome numbers running in an arithmetical series, with 9, 18, and 27 pairs. A species with 27 pairs, *Beta trigyna* Waldst. and Kit., exhibited a sugar content almost twice as great as that of the best commercial varieties of sugar beets. From the plant breeder's standpoint this information indicates that there are still untried species in the wild origin centers that offer new characters for hybridization and selection. Moreover, the occurrence of chromosome numbers in arithmetical series suggests the operation of chromosome doubling in the evolutionary history of the genus and gives hope of producing new constant-breeding hybrids made to order.

BREEDING OF THE CARROT

Although the home of the carrot, *Daucus carota* L., is western Asia, all of our present varieties represent western European selections, many of which were made by Vilmorin, a French plant breeder and seedsman of the middle nineteenth century. Up to the present, carrot breeding has been almost entirely a matter of crude mass selection, based on the appearance of roots at the end of the first season's growth.

This method has produced a surprisingly good range of varietal types in length and shape of roots, relative thickness of central core, color of roots, and length of time from planting to market maturity. Because of the increasing demand for carrots in the dietary, however, much attention is being given today to the more modern methods of inbreeding for the purification of commercial stocks and for genetic analysis, followed by cross-pollination.

Some notion of the uniformity developed in inbred carrot lines may be gained from the fact that the coefficient of variability in carotene content (carotene is a yellow coloring matter and the source of vitamin A) between 28 roots of a commercial strain of Danvers Half Long was about 33 percent, while the variability between 28 roots of a line inbred for four generations was only about 7 percent.[4]

The leading carrot varieties over the last 20 years have been Chantenay, Danvers Half Long, Oxheart, and Nantes, all of which are medium long, require from 70 to 75 days from planting to marketing condition, and vary from a large core in Chantenay to a minimum of core in Nantes. Although the present trend is to develop narrower cores, there is a limit, because an increasing brittleness of the tops accom-

[4] Influence on carotene content of inbreeding 4 generations (after Emsweller, Burrell, and Borthwick, *6*):

Statistics calculated		Commercial strain	Inbred line
Roots separately analyzed	number	28	8
Mean carotene content	mg. 100 g dry matter	66	56
Range in carotene content	do	32–164	36–80
Standard deviation	do	23.00	4.06
Coefficient of variability	percent	33.6±3.3	7.0±0.6

The average carotene content per line among 18 inbred lines descended from 2 original plants varied from 32 to 63 mg per 100 g of dry matter. One may infer from the above that lines derived from more than 2 original plants would have given a greater spread and therefore offer even better inbred lines with higher carotene content.

panies an increasing narrowness of core. The carrot is the last of the root vegetables to receive the attention of geneticists, owing largely to misconceptions of the difficulties involved. Selected plants were allowed to set seed by open pollination because it was believed that carrots were self-incompatible, and this practice, of course, has largely nullified the effects of the root selection.

For many years carrot growers and seedsmen did not understand that the failure of isolated umbels to set seed was due not to self-incompatibility but to the fact that the stamens of a carrot flower ripen and shed their pollen some hours or days before the pistil is receptive to pollen. Consequently, self-pollination is effective only if the stigmas of the older flowers can be served by pollen from the anthers of younger ones. This service is performed by blowflies introduced into cages in which the entire plant or a major branch is encased; and by using this technique which is described in more detail later, Borthwick and Emsweller (*2*) demonstrated that all carrot varieties tested were entirely self-fertile.

Miller (*28*), in Louisiana, in working with the problem of poor color in carrots grown on certain soils, found that merely selecting the best colored roots on soil that was adversely affecting color produced progenies (whether self-pollinated or open pollinated) having higher percentages of well-colored roots on unfavorable soils than check commercial strains.

Recent studies indicate that hybrid vigor in the carrot acts as it does in corn. When two inbred lines producing roots averaging 12.8 and 24.9 g, respectively, were crossed, the first-generation progeny produced roots that weighed 80.5 g on the average.

Genetic analysis in the carrot has included studies of the inheritance of such characteristics as branched roots, cracked roots, root shape, and root color.

IMPROVEMENT OF OTHER ROOT VEGETABLES

Among the root vegetables taro, parsnip, and salsify are relatively unimportant in the United States, and the number of contrasting characters available for study is so small that no attention has thus far been paid them by breeders or geneticists.

Varieties of Taro

The taro, or dasheen, *Colocasia esculenta* (L.) Schott, seems to have three centers of origin, China, India, and South America, and up to very recent times its cultivation was practically confined to the Hawaiian and other Pacific Islands, where its fleshy root is the staple food of the natives, and also to the Mediterranean region. Recently, however, several introduced varieties of the taro, Trinidad, Ventura, and Sacramento, were thought sufficiently promising to serve as potato substitutes in the Southeastern States (*43*, *44*). As early as the seventeenth century a few varieties were successfully grown in South Carolina as a cheap food source for the plantation hands, but the industry failed to meet competition with importations from the West Indies. The starch of the root is regarded in Hawaii as superior to that of any other root vegetable in the ease with which it is digested and assimilated. Young (*43*) gives many ways in which the taro root may be prepared

as a food, including practically all the ways used with the potato and the sweetpotato.

No breeding or genetic work has been done with taros, and only in Hawaii is there any record of seed production. Moreover, many varieties of taro fail to produce an inflorescence, even in Hawaii. The United States Department of Agriculture has recently begun a project on taro breeding with the object of introducing a large number of species and varieties from Hawaii and elsewhere with a view to investigating their genetics and cytology, and also to provide new varieties with appeal to the growers and consumers of the Southeastern States.

The Parsnip

The parsnip, *Pastinaca sativa* L., is a relatively unimportant root vegetable cultivated in the United States as a market garden crop. Records show that its center of origin was the Mediterranean region and that it was introduced into Virginia in 1609 and Massachusetts in 1629, but thus far there has been no interest in the improvement of varieties or in the analysis of character inheritance. Only one variety of importance, Hollow Crown, is grown in this country, and the lack of varieties with character contrasts is one reason for the failure of geneticists to attempt any character analysis.

The parsnip is an umbelliferous plant in the same family as the carrot, and like the carrot it exhibits the phenomenon of protandry, the pollen being shed long before the stigmas are receptive. The pollination technique of producing pure strains for variety improvement or genetic analysis is therefore identical with that for the carrot.

Salsify

Salsify (*Tragopogon porrifolius* L.) or vegetable-oyster—so called because of a mildly oysterlike flavor—is grown in the United States on a very small scale and is represented mainly by a single variety, Mammoth Sandwich Island. Salsify originated in the Mediterranean area, and its introduction into the United States first occurred about 1806. Practically all the salsify seed produced in this country comes from a narrow strip along the coast of central California. Its limited use, as well as the meager representation of character differences, accounts for the failure of plant breeders or geneticists to take any interest thus far in its improvement.

Salsify is one of the Compositae, belonging to the same family as the sunflower. Its fleshy taproot, which resembles a small parsnip, is handled for curing and storing very much like the dahlia root.

SOME INTERESTING ASPECTS OF ROOT-CROP BREEDING

In spite of the limited amount of practical breeding work with the root vegetables, there are certain aspects of the breeding technique and of the theoretical knowledge attained that are exceptionally interesting from the standpoint of plant breeding in general. An effort will be made here to discuss these aspects as simply as possible for the nontechnical reader. (A technical discussion of root-crop genetics follows later in this article.)

Inbreeding in the root crops is often difficult for two reasons. (1) It brings out recessive factors for small size and lack of vigor; in other words, it is just as likely to make undesirable factors "pure" as desirable ones. Inbred lines frequently are so enfeebled that they cannot live. In carrots, for example, this is so general as to make it necessary to proceed with caution in inbreeding and to inbreed several generations, then outcross to secure enough vigor to go on, then continue inbreeding until the line is as uniform and homozygous or "pure" as desired. With beets, on the other hand, many vigorous upstanding inbred lines have been selected without recourse to outcrossing. (2) Inbreeding may also uncover recessive hereditary factors for self-incompatibility.

How do these factors for self-incompatibility act? In the cruciferous vegetables—including turnip, rutabaga, radish—and probably beets, the rate of pollen-tube growth of all pollen grains containing such a factor is retarded if that factor is also present in the tissues of the style (the stalk of the pistil) through which the pollen tube has to grow before it can reach the ovary; in other words, if the factor is present in both male and female cells (fig. 2). When the rate of pollen-tube growth is retarded the male cell cannot reach the female cell in time to effect fertilization. Self-pollination is thus impossible in plants that lack the normal alternative (allelomorph) of these self-incompatible genes. The difficulty can be overcome, however, by bud pollination; that is, applying pollen to the stigmas of unopened buds. This permits many extra hours of pollen-tube growth before the flower would normally shed its own pollen.

Commercial varieties that contain genes for self-incompatibility cannot be pure or homozygous for this characteristic or they could not reproduce by crossing with other plants of the same variety. They must in some way be cross-compatible with other plants of the variety; that is, in a highly heterozygous condition so far as the genes for self-compatibility are concerned. The best way to remedy this situation is to remove the factors for self-incompatibility that prevent reproduction, by making appropriate crosses to stocks containing the "normal" alternative genes or allelomorphs; or, more simply, all lines that are not self-fertile may be eliminated. The situation is illustrated in figure 2.

The last method has been shown to be entirely feasible even in such characteristically self-incompatible species as cabbage and beets. In these species numerous varieties are available that are completely self-fertile.

All our common root vegetables are biennials, and this somewhat reduces the speed with which breeding operations may be conducted. In each case there are also special impediments to breeding operations, such as self-incompatibility in the cruciferous species, self-incompatibility and wind-pollination in beets, difference in the time of maturity of the male and female organs in carrots, and failure of taro to produce flowers when grown in most regions. These handicaps, however, merely tax the ingenuity of the vegetable breeder and make it necessary for him to develop a special pollination technique for almost every species. To appreciate some of the problems confronting the vegetable breeder, it will be well to review the pollination tech-

nique now most favored for cross-pollination or self-pollination in the root vegetables.

The cruciferous root vegetables—turnips, rutabagas, and radishes—have relatively large flowers, which are insect-pollinated. This makes it necessary, in order to effect controlled pollination, to isolate all flowers from insect contamination by encasing them in cloth or paper bags or in cages made of netting. Crawling insects may be excluded by gluing a cotton lining on the inside of the neck of the bag.

To cross-pollinate, the six anthers from the flower of the female parent must be removed a day before the pollen is shed, thus preventing any chance of self-pollination. The following morning the pollen from the intended male parent, which likewise has been bagged, is applied, either by a camel's-hair brush or by transferring an entire flower that is shedding its pollen, to the stigma of the emasculated flower of the seed parent.

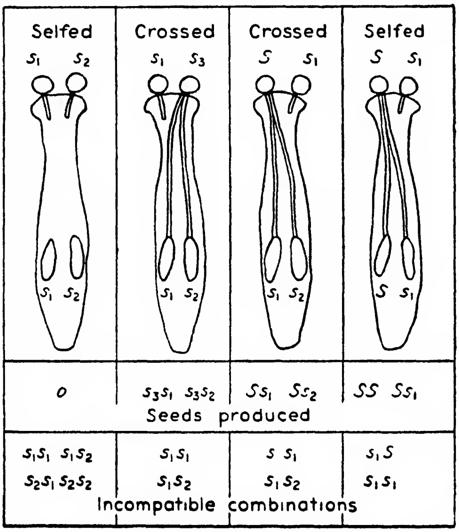

Figure 2.—Diagram showing possible combinations in crosses involving self-incompatibility. *S* represents the normal self-compatible genes, dominant to all the members of the multiple allelomorphic series. s_1, s_2, and s_3 represent self-incompatible genes, recessive multiple allelomorphs of *S*. No plant can have more than two (any two) members of this series.

To self-pollinate, it is necessary, as before, to isolate all flowers from insect contamination. If the plant is self-compatible, it will automatically pollinate itself. If it is self-incompatible, however, it will be necessary to bud-pollinate; that is, to apply pollen from a flower opened this morning to an as yet unopened bud of the same plant. The pollen will thus have extra time in which to reach the ovules. It is even possible that the retarding principle does not become effective until after the pollen of a given flower is shed normally.

The beet is an example of a wind-pollinated species that is also insect-pollinated to some extent. Beet pollen is so small and dust-like that samples of it have been found by airplanes at elevations of 1,000 feet. Consequently when air currents are in motion the removal of a bag in order to effect pollination, even for an instant, may result in contamination of the stigmas with undesired foreign pollen. The best practice is to pollinate in still air; for example, within a greenhouse. The floral organs are so small that emasculation is impracticable. When cross-pollination is desired, an excellent procedure is to make a cross with a male parent that has some easily identified, dominant characteristic. All progeny that result from self-pollination will then show the recessive characteristic and can be discarded in favor of the hybrids, which can be identified by the dominant characteristic; or if it is not completely dominant, they will be intermediate in character.

The technique developed for sugar beets by Brewbaker (*3*) is to isolate the female parent flowers in a hand-made bag 5½ inches by 17 inches made of 30-pound vegetable parchment. When cross-pollination is desired, the danger of uncontrolled pollination may be practically eliminated by not removing the bag at all, and blowing pollen into it with a pollen gun, as described by Jenkins (*13*). As already explained, self-incompatibility in beets and crucifers prevents successful self-pollination unless a normal alternative gene (allelomorph) is present. A strain with such a normal gene might be called a low self-fertile one, and, as indicated in figure 2 (the fourth ovary from the left), a low self-fertile strain may be converted by inbreeding and selection into a high self-fertile strain containing only the dominant normal gene; that is, a strain homozygous for self-fertility.

As a result of inbreeding experiments with sugar beets, Brewbaker (*3*) says: "The characters of high and low self-fertility appear to be heritable, and by selection and continued self-pollination highly self-fertile lines would be obtained." It should be said that no genetic analysis of the inheritance of what is called self-sterility in beets has been made, but it is assumed to be of the same nature as that outlined in figure 2, which in general illustrates the interaction of genes for self-incompatibility in the cases thus far studied, tobacco and cabbage.

In carrots no self-incompatibility is encountered, despite previous beliefs (*2*). Self-fertility is complete provided one overcomes the barrier of protandry, which can be easily done by using the fly-pollination technique of Jones and Emsweller as applied to carrots by Borthwick and Emsweller (*2*), for either cross-pollination or self-pollination.

Since carrot flowers are as small and difficult to emasculate as beet flowers, cross-pollination is effected most readily by bagging single umbels in muslin or cheesecloth bags, waiting several days after the first flowers have come into full bloom, then introducing an umbel of the male parent with cut stem in a jar of water, along with a supply of freshly hatched clean blowflies, which will effectively transfer the pollen to the female umbels. In such cases self-pollination is impossible on a single umbel because of the existence of protandry. Self-pollination is readily performed by caging an entire plant in a muslin or cheesecloth bag, then periodically introducing clean freshly hatched flies. By caging the entire plant the flies are enabled to pollinate the older flowers with their own kind of pollen from the younger flowers.

The technique of pollination in taros is very simple. The taro flower is in the form of a spadix or fleshy axis enclosed by a modified leaf or spathe, as in the jack-in-the-pulpit or the calla. Each spadix contains staminate florets on its upper end and pistillate florets on its lower end. All that is required is to remove the spathe and enclose the spadix in a glassine or other transparent bag to exclude insects, and self- or cross-pollinate the female florets as desired with a camel's-hair brush. This is sometimes impossible on a single spadix because in some species of taro the stigmas are past receptivity by the time pollen is ready. (This is known as protogyny, the opposite of protandry.) As a precaution against self-pollination when crossing is desired, it is

advisable to remove the male end of the spadix. The real difficulty with taro, however, is that most varieties will not produce an inflorescence even where they are extensively cultivated, as in Hawaii.

Hybridization between species or genera of the root vegetables has produced at least three artificial hybrids with all of the chromosomes doubled. Plants with doubled chromosome numbers of this kind are known as amphidiploids, and they are usually hybrids between remotely related parents. It would seem that on account of the remote relationship, the chromosomes of the parents are so dissimilar as to be unable to mate or pair properly. The cell-division mechanism is consequently so fundamentally disturbed as to produce a doubling of the number of chromosomes in the sex cells. The first-generation hybrid is likely to be either entirely sterile or almost so, but the doubling of the chromosome number provides all unmated chromosomes with mates for pairing, so that in future generations sex cell division can proceed in the regular manner. The result may be a true-breeding amphidiploid. In figure 3 all visibly unpaired chromosomes of the F_1 or first hybrid generation can be seen to be doubled in the amphidiploid hybrid. Frequently, however, the chromosome doubling takes place in the cells of the plant body instead of in the sex cells.[5]

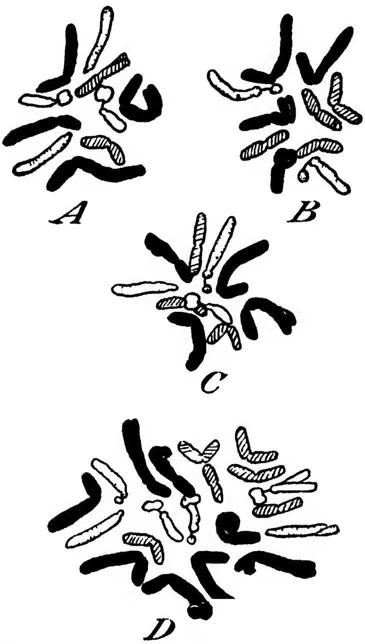

Figure 3.—Somatic (diploid) chromosome sets of two parent species of hawks-beard: *A*, *Crepis rubra*; *B*, *C. foetida*; *C*, their F_1 hybrid; *D*, their amphidiploid hybrid. Chromosome doubling in some F_1 sex cells, followed by a union of two of them, has produced a complete diploid set, qualitatively as well as quantitatively, from both parents. × about 1,800.

It was only in 1925 that the first amphidiploid hybrid obtained under experimental conditions was recognized and described (*4*). Since then an almost bewildering number of such hybrids have been described. Many of them, because of the wide separation of their two parents, are practically true-breeding and might truly be called new genera or new species and given new names (*42*). In other cases, however, the parent species were so closely related to begin with that many of the chromosomes were able to pair, and the subsequent chromosome doubling therefore only resulted in a more complex hybrid, but not a true-breeding one or one that could be expected to produce stable derivatives (*31*, *32*).

Many plant genera contain species whose sex cell chromosome numbers occur either exclusively or mostly in multiples of some common number. In wheat (*Triticum*), for example, some species

[5] That is, amphidiploids may be formed in two ways—in the gametophyte or sexual generation, and in the sporophyte or asexual generation.

have 7 chromosomes, others 14, and still others 21, in an arithmetical series. Other examples of genera in which this occurs, with the sex cell chromosome numbers, are:

Beta (beet)	9, 18, 27
Campanula	17, 34, 51, 8, 16, 10, 13
Chrysanthemum	9, 18, 27, 36, 45
Papaver (poppy)	7, 14, 21, 28, 11, 22
Rosa	7, 14, 21, 28

The occurrence of arithmetical series among the chromosome numbers of many genera prompted Winge in 1917 to offer the hypothesis that such chromosome numbers arose as a consequence of chromosome doubling following species crosses. At that time he knew of no experimental verification of his hypothesis, but now there are scores of artificially produced amphidiploids, as well as evidence of amphidiploid hybrids in the wild, and correlated analyses of characters and chromosome numbers for their parent species. Two species known to be natural hybrids are successfully growing in the wild—one a pentstemon, in the foothills of California, and the other a grass, in the harbors and on the beaches of the English Channel. The artificially produced constant breeding amphidiploids in the Cruciferae, with the number of pairs of chromosomes, are:

(1) Radish, *Raphanus sativus*, 9 pairs, × cabbage, *Brassica oleracea* L., 9 pairs, produced "*Raphanobrassica*", 18 pairs.
(2) Radish, *R. sativus*, 9 pairs, × Chinese cabbage, *B. chinensis* L., 10 pairs, produced "*Brassicoraphanus*", 19 pairs.
(3) Turnip, *B. campestris* L., 10 pairs, × rutabaga, *B. napus*, 18 pairs, produced "*Brassica napocampestris*", 28 pairs.

Although none of these constant breeding hybrids has commercial possibilities at present, *Brassica napocampestris*, combining features of the turnip and the rutabaga, may easily have value with further selection, and the others can be used as parents for further crosses to provide selection material for commercial stocks.

The fact that the chromosome numbers in *Beta*, from which our garden and sugar beets come, occur in an arithmetical series, 9, 18, 27, suggests that species formation in this genus was influenced to some extent by chromosome doubling following crosses between species.

GENETICS OF THE ROOT VEGETABLES [6]

Turnip and Rutabaga

According to Kajanus, turnip more commonly contains hereditary factors for self-incompatibility than rutabaga. This is expected if among the larger number of chromosomes of the rutabaga the chromosome containing the locus S versus s_1, s_2, etc. (see fig. 2), had been duplicated; hence segregations for compatibility versus incompatibility will show at least a tetraploid rather than a diploid ratio; for example, an expectation of 35:1 instead of 3:1. The production of self-fertile inbred lines in turnips will, therefore, be more difficult than in rutabagas.

Kajanus (*15, 16, 17, 18, 19*) has made the greatest number of genetic analyses in both these species, the main results of which are shown

[6] This section is written primarily for students or others professionally interested in breeding or genetics.

138004°—37——21

in tables 1 and 2. Among other geneticists who have worked with these vegetables are Hallqvist (*11*, *12*), Malinowski (*25*, *26*), and Sylven (*34*). Kajanus studied the progeny of hybrids between these two species, and Frandsen and Winge (*8*) produced an F_1 hybrid between the turnip and the rutabaga that later doubled its chromosome number. The ensuing amphidiploid stock of plants had the potentialities of a constant new species, combining features from both parents, but most of them came from the rutabaga, because it contributed most of the chromosomes.

TABLE 1.—*Genetic analyses of character inheritance in turnip*

Symbols	Phenotypes		
	Color of bark	Color of flesh	Color of flower
PVM	Red	White	Yellow
PVm	do	Yellow	Orange
PvM	do	White	Yellow
Pvm	do	Yellow	Orange
pVM	Green	White	Yellow
pVm	do	Yellow	Orange
pvM	Yellow	White	Yellow
pvm	do	Yellow	Orange

M v. m, white *v.* yellow flesh color, also yellow *v.* orange flower color
P v. p (anthocyanin), red *v.* cream-yellow upper root bark color.
V v. v (chlorophyll), green *v.* cream-yellow upper root bark color
P is epistatic to *V*, thus producing the phenotypic combinations shown above.
Mendelian ratios obtained (Kajanus):

Bark color—12 red : 3 green : 1 yellow.
Flesh color—3 white : 1 yellow.
Flower color—3 yellow : 1 orange.
Root shape—multiple factor inheritance
Root surface—3 cracked : 1 smooth.

The heterozygotes of these genes exhibit an intermediate intensity of expression; consequently the classification of any hybrid population may be more complex than is indicated.

TABLE 2.—*Genetic analyses of character inheritance in rutabagas*

Symbols	Phenotypes			
	Color of bark	Color of flesh	Shape of leaf	Color of flower
$P_1P_2M_1M_2E_1E_2AB$	Deep red	White	Pinnatifid	Yellow
$p_1P_2M_1M_2E_1e_2Ab$	do	do	do	Orange
$P_1P_2M_1m_2e_1e_2aB$	do	do	Entire	Pale yellow
$P_1P_2m_1M_2E_1E_2ab$	do	do	Pinnatifid	Pale orange
$P_1p_2M_1M_2e_1e_2AB$	Pale red	do	Entire	Yellow
$P_1p_2M_1m_2e_1e_2Ab$	do	do	do	Orange
$p_1p_2M_1M_2E_1e_2aB$	Green	do	Pinnatifid	Pale yellow
$p_1p_2m_1m_2e_1e_2ab$	do	Yellow	Entire	Pale orange

A v. a, orange *v.* pale orange flowers.
B v. b, yellow *v.* pale yellow flowers.
P_1 *v.* p_1, pale violet red *v.* green.
P_2 *v.* p_2, deep violet red *v.* green.
M_1M_2 *v.* m_1m_2, yellow *v.* white flesh color.
E_1E_2 *v.* e_1e_2, pinnatifid *v.* entire leaf outline.
P_2 is epistatic over P_1, giving the phenotypes shown above.

Mendelian ratios obtained:

Bark color—12 deep red : 3 pale red : 1 green (Kajanus and Hallqvist).
Flesh color—15 white : 1 yellow (Hallqvist).
Leaf shape—15 pinnatifid : 1 entire (Hallqvist).
Life cycle—Biennial *v.* annual, multiple factors (Malinowski).
Flower color—9 yellow : 3 orange : 3 pale yellow : 1 pale orange (Sylven).

The duplicate nature of factorial relations here is an additional reason for the suggestion that the genes concerned are included in the extra set of eight chromosomes by which the rutabaga is distinguished from the turnip. For example, the two 15:1 segregations for flesh color and leaf shape indicate duplicate dominant genes for the dominant allelomorphs in each case. Malinowski, who analyzed the cross biennial × annual, obtained an observed ratio of 349 biennials to 57 annuals, which gives a significant deviation from any assumed Mendelian ratio.

Turnip × Rutabaga Crosses

From 1912 to 1917 Kajanus reported studies from a number of crosses between the two species, turnip, *Brassica rapa* (10 pairs of chromosomes), and rutabaga, *B. napus* (18 pairs of chromosomes), with results that have been summarized by Matsuura (*27*). The work was done before the acceptance by geneticists of cytological aid in investigating crosses between parents with differing chromosome numbers. The studies summarized by Matsuura would have been more valuable had the investigators considered this feature of the problem. Most of the analyses made, however, deal only with simply inherited leaf characters that segregate in the F_2 generation with 1:2:1 monohybrid ratios, as, 1 pubescent : 2 intermediate : 1 smooth; or 1 bloom : 2 intermediate : 1 nonbloom.

The Amphidiploid Hybrid "Napocampestris"

In 1932 Frandsen and Winge (*8*) reported the production under experimental control of a hybrid between the turnip, *Brassica campestris* var. *sativa rapifera* (10 pairs of chromosomes) and the rutabaga, *B. napus* var. *sativa rapifera* (18 pairs of chromosomes). It is unfortunate that an unnecessary confusion should be introduced by calling the turnip *B. campestris* here and *B. rapa* at other times, but the authors' names have been used. As expected, plants of the first filial generation were, as a rule, quite sterile compared with the parent plants. One of the F_1 plants, however, proved to be almost as fertile as the parents. A cytological examination of the root tips of several F_1 plants showed the expected chromosome number of 28 (10 plus 18), where half the chromosomes from rutabaga were added to half the number from the turnip parent. Consequently it is believed that all the F_1 plants, with the exception of the one that was highly fertile, possessed 28 somatic chromosomes. The highly fertile plant is believed to have doubled its chromosomes from 28 to 56 immediately following fertilization, as in *Nicotiana digluta* (*4*), because in the progeny of this plant 21 plants that were examined cytologically were highly uniform both as to outward appearance and as to the chromosome number of 56.

The progeny of all 28-chromosome F_1 plants exhibited a more or less high degree of sterility, because at the time of formation of sex cells the 18 chromosomes from the rutabaga parent had only 10 chromosomes from the turnip parent with which to mate, leaving 8 chromosomes to be distributed to the sex cells at random. Consequently, when these plants were self-pollinated, all sorts of fertilizations with odd chromosome numbers were effected, many of which proved to be nonviable, hence the high degree of sterility. Sterility of this kind is called "generational" sterility, to distinguish it from incompatibility, already considered. In the progeny of the 56-chromosome fertile plant, however, the distribution of chromosomes to the new sex cells was as regular as though the plant had 28 pairs of chromosomes, the members of each pair separating from each other at germ cell formation with the regularity of true-breeding natural species.

An idea of the uniformity of this fairly true-breeding new hybrid may be gained by comparing its F_2 progeny with the parents and the F_1 generation.

Rutabaga: Oval root, red-violet bark, yellow flesh.

Turnip: Elongated root, green bark, yellow flesh.

F_1 (a): The seed of two plants gave half-long roots, red-violet bark, and yellow flesh in the progeny.

F_1 (b): The seed of one plant gave half-long roots, one-half red-violet and one-half green bark, and yellow flesh.

F_2 generation is shown in table 3.

TABLE 3.—*Distribution of root shapes of turnip-rutabaga hybrids*

Nature of hybrid	Globe	Oval	Half long	Long conical	Bark color
	Percent	*Percent*	*Percent*	*Percent*	
Diploid	17	18	53	12	Various
Amphidiploid			84	16	Green

In outward appearance as well as in chromosome content most of the progeny, diploid or amphidiploid, resembled the rutabaga parent which contributed eight more chromosomes than the turnip. This may be compared to the observation that in The Bruce turnip most of the characters usually favor the presumed rutabaga parent. From the foregoing discussion of Kajanus' analysis of inheritance of root color in turnips and rutabagas it is seen that green bark is hypostatic to red bark, which indicates that the rutabaga parent of Frandsen's amphidiploid hybrid must have been heterozygous for the red bark factor, and therefore of the genotype *PpVV*.

GENETICS OF THE RADISH

An outline of the chief genetic analyses in the radish, *Raphanus sativus*, together with the names of the investigators reporting them, is given in table 4. The list is compiled chiefly from the work of Frost (*9*), Uphof (*39*), and to a lesser extent Malinowski (*25*) and Karpechenko (*21*, *22*). The character contrasts include all organs of the plant, and the segregations reported show that a fairly simple factorial situation usually exists.

Some question arises regarding the interpretation of results from the cross red-striped *v.* white (made from crossing the variety Triumph with either Early White or Icicle). In F_1 red-striped was completely dominant to white, but in F_2 instead of 3 red-striped:1 white, Uphof obtained 1 red-striped:1 white. No cause of the supposed disturbed ratio was learned, but Uphof suggested the action of a gamete lethal, although this ratio might actually be a 9:7 interaction, in which two recessive whites are involved. Frost's crosses in some cases showed a pronounced hybrid vigor in F_1, a phenomenon most frequent in open-pollinated species maintained in a highly heterozygous state.

TABLE 4.—*Character inheritance in Raphanus sativus*

P_1 characters	F_1	F_2	Investigator
Root			
Yellow *v.* white	Yellow	3 yellow 1 white	Uphof, Malinowski
Red *v.* white	Purple	1 red 2 purple 1 white	Uphof

Inflorescence:			
White *v.* yellow	White	3 white 1 yellow	Karpechenko
Woody capsule *v.* papery	Woody	Complex inheritance	Frost

Linkage —Purple *v.* red and early *v.* late are on the same chromosome

Species Crosses in the Radish

Crosses are easily made between the wild radish, *Raphanus raphanistrum* L., yellow flowered, and the cultivated radish, *R. sativus*, red, purple, or white flowered. Both species have nine pairs of chromosomes, and the cross appears to segregate regularly both as to chromosome distribution and Mendelian factors. F_1 interspecific hybrids usually have violet flower color, and, according to Trouard-Riolle (*36*, *37*), the starchy root of the wild radish is dominant over the sugary root of the cultivated radish. Frost found indications of a linkage between the locus for purple-red root pigment and that for earliness *v.* lateness of flowering, with a cross-over of 4.78 percent. Frost also established the presence of self-incompatibility in the radish, but made no analysis of its genetics.

Karpechenko's "Raphanobrassica"

Karpechenko (*21*) obtained a first-generation hybrid between the radish ($2n=18$) and cabbage ($2n=18$) which was highly sterile as a result of disparity in chromosome content and structure, although not in chromosome number, between the two parent species. In consequence of the cell-division disturbances, some of the functioning sex cells had double the expected number of chromosomes. The chance conjugation of two such unreduced sex cells resulted in the production of a plant having the combined diploid number of chromosomes of the two parents, known as an amphidiploid hybrid. Karpechenko's amphidiploid hybrid was in some respects like the

amphidiploid hybrid that Frandsen obtained in the turnip-rutabaga cross already described. There is one important difference, however, between Karpechenko's radish-cabbage amphidiploid and Frandsen's turnip-rutabaga amphidiploid. Frandsen's hybrid presumably resulted from a suspended cell division following the union of the turnip sperm with the rutabaga egg, whereas Karpechenko's hybrid resulted from the chance meeting of two unreduced sex cells in the ovary of a first-generation hybrid. Thus we have illustrations of the two ways in which amphidiploids can be produced; (1) where the doubling occurs in the asexual or sporophyte generation, and (2) where the doubling occurs in the sexual or gametophyte generation.

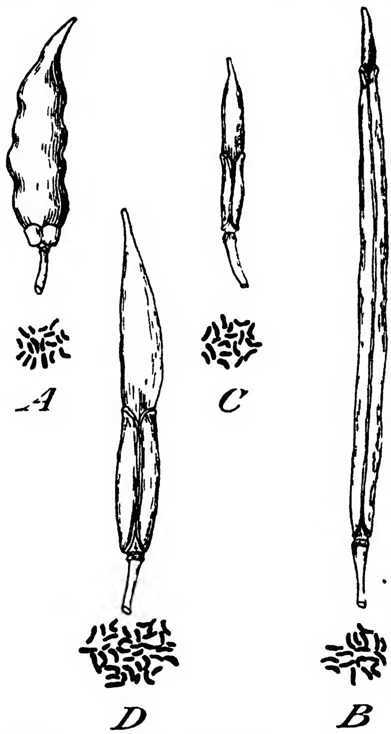

Figure 4.—Diagrammatic representation of the relative capsule shapes and sizes, as well as chromosome numbers, in (*A*) *Raphanus sativus*, (*B*) *Brassica oleracea*, (*C*) their F_1 hybrid, and (*D*) their amphidiploid hybrid. Redrawn from Karpechenko, but the relative chromosome sizes were somewhat enlarged in the copying.

Figure 4 presents a diagram of the types of seed capsules characteristic of the parents and hybrids occurring in the production of Karpechenko's amphidiploid, which he called *Raphanobrassica*. The hybrid plants were clearly intermediate between the two parents in the structure of capsules, as will be seen from figure 4, but also in possessing as many kinds of chromosomes from one parent as the other—radish, *Raphanus satirus* ($2n=18$); cabbage, *Brassica oleracea* var. *capitata* ($2n=18$); *Raphanobrassica* ($2n=36$).

No effort has been made to utilize *Raphanobrassica* to improve either the radish or the cabbage, and Karpechenko (*22*) states that it will not cross back to either of its parents. It will cross readily, however, with a large number of other cruciferous species, including turnips and rutabagas, which in turn will not cross with either radish or cabbage. Karpechenko attempted to produce still other amphidiploids with an even higher chromosome number by adding the chromosomes of turnip, rutabaga, etc., to those of *Raphanobrassica*. The first-generation hybrids have succeeded, but thus far the chromosome doubling to stabilize sex cell formation has not occurred.

From the plant-breeding standpoint the chief value of these studies is the demonstration of the principle that if a cross cannot be made directly between species *A* and *B* because of their wide evolutionary separation, then the gap may be bridged by first forming a hybrid between *A* and *C*, with which *B* will later successfully cross.

Terasawa's "Brassico-raphanus"

In 1932 Terasawa (*35*) reported the appearance of an amphidiploid hybrid called *Brassico-raphanus* with $2n=38$ chromosomes, which bred approximately true in the F_4 generation from the cross pakchoi (*Brassica chinensis*, $2n=20$) × radish (*Raphanus sativus*, $2n=18$). He explained the tardy appearance of this amphidiploid in F_4 instead of F_2 as resulting from insect pollination of F_2 plants, which somehow induced nonreduction of chromosomes in sex cells. Consequently, the origin of *Brassico-raphanus* from unreduced gametes was in the main similar to that of *Raphanobrassica*. The phenotypes of the two parents and their intermediate hybrid are shown in table 5.

TABLE 5.—*Comparative morphology of Brassica chinensis, Raphanus sativus, and their amphidiploid*

Species	Leaf margins	Roots	Flower color	Calyx	Fruit structure
Brassica chinensis	Entire	Slender	Yellow	Open	2 locules.
Raphanus sativus	Lobed	Fleshy	Purple	Closed	Not dehiscent.
Brassico-raphanus	Intermediate	Quite fleshy	White with purple veins	Intermediate	Upper half not dehiscent, lower 2 locules.

GENETICS OF THE BEET

Our knowledge concerning the genetics of *Beta* is obtained chiefly from the investigations of Kajanus (*14, 16, 20*) and Keller (*23*). Some years ago Kajanus, also Lindhard and Iversen (*24*), investigated the inheritance of root color in this biennial root crop, and all believed that the postulation of two pairs of factors was sufficient to account for color inheritance. Certain discrepancies in Kajanus' segregation, which he ascribed to faulty pollination technique, were observed also by Lindhard and Iversen, who interpreted them as caused by about 37-percent linkage between the two postulated loci. More recently, however, Keller, with greater care against the contamination of wind-pollination, investigated the genetics of root color. Instead of only the two pairs of factors assumed by Kajanus et al., giving 4 segregating phenotypes in F_2, he finds that each of the two loci carries a series of three multiple allelomorphs.

The genes postulated by Keller in the order of their dominance are:

Locus 1. R=red hypocotyl, R^t=red top white hypocotyl, r=yellow hypocotyl.
Locus 2. Y=yellow root, Y^r=green top yellow root, y=white root.

From two different F_2 populations the following series of nine phenotypes was obtained from combinations of these six genes:

Root phenotypes in garden-beet crosses

Phenotypes	*Symbols*
Red hypocotyl, white root	Ry
Red hyopcotyl, red root	RY
Pale red hypocotyl, pale red root	$RY\pm$
Striped red beet	R^tY^r
Green top, red root	RY^r
Red top, white root	R^ty
Yellow hypocotyl, white root	ry
Green top, yellow root	rY^r
Yellow beet	rY

Moreover, instead of a loose linkage of 37 percent, he calculated an average linkage of 7.3 percent for four crosses made in the coupling phase and a linkage of 8.8 percent for a single cross made in the repulsion phase. Different members of the multiple allelomorph series were used in the two types of crosses, as shown in table 6.

TABLE 6.—*Linkage values derived from beet crosses in the coupling and repulsion phases*

Crosses	Parental combinations		Recombinations		Total
	R^tY^r	ry	R^ty	rY^r	
Coupling phase crosses. Recombination percentage=7.3:					
$\frac{ry}{ry}\times\frac{R^tY^r}{ry}$	97	114	14	5	230
$\frac{R^tY^r}{ry}\times\frac{ry}{ry}$	145	137	7	12	301
$\frac{ry}{ry}\times\frac{R^tY^r}{ry}$	89	162	9	8	268
$\frac{R^tY^r}{ry}\times\frac{ry}{ry}$	133	109	12	11	265
Total	464	522	42	36	1,064
	Ry	rY^r	RY^r	ry	
Repulsion phase cross. Recombination percentage=8.8:					
$\frac{Ry}{rY^r}\times\frac{ry}{ry}$	315	307	23	37	682

Kajanus also investigated the genetics of leaf color, but found the ratios less satisfactory than for root color. In the red-fleshed beets the distribution of anthocyanin is sometimes general throughout the stems and leaves and sometimes confined to the stems, petioles, and larger veins, the rest of the leaf being green. Crosses between red-containing phenotypes and entirely green-leafed ones gave conflicting results. Sometimes green appeared to be dominant to red and at other times it was clearly recessive. He interpreted this paradox to indicate the presence of a dominant inhibitor for red leaves in some genotypes which is absent in others.

Finally, for root shape, Kajanus postulated four pairs of genes:

L v. l, long root *v.* short.
O v. o, inhibitor of *L v.* noninhibitor.
A v. a, sharp *v.* blunt forms.
B v. b, inhibitor of *A v.* noninhibitor.

It has already been noted that the root crops carry several genes for self-incompatibility, and *Beta vulgaris* is no exception. Although no attempt has been made to study the inheritance of self-incompatibility in *Beta*, it is easy to keep these genes out of the populations by selecting self-fertile inbred lines. The Division of Sugar Plant Investigations of the Bureau of Plant Industry has selected several completely self-fertile strains of sugar beets, and Roy Magruder, of the Division of Fruit and Vegetable Crops and Diseases, has several promising inbred lines of garden beets.

Dudok van Heel (*5*) with sugar beets and Bateson (*10*) with sugar, garden, and stock beets, have investigated the inheritance of bolting. Both investigators thought inbreeding in beets was impossible because of self-incompatibility, and thus made their selections from open-pollinated mother plants. Despite the poor pollen control, both were able in a short time to select lines that were practically or entirely nonbolters under any conditions. Bateson rapidly eliminated bolters by forcing under glass. Dudok crossed high-bolting and low-bolting strains and found evidence in F_1 that low bolting or nonbolting was dominant, but he attempted no further analysis.

In view of the fact that in radishes Frost found high bolting to be completely dominant to low bolting in the ratio of 3 : 1 in F_2, and that in rutabagas Malinowski found low bolting partially dominant in F_1 and F_2 with indication of multiple factors, it is regrettable that more complete information is not available for beets. It is probable that many genetic factors are in operation, from the fact that a wide range exists between beet varieties in length of time to market maturity.

Genetics of the Carrot

The project of producing inbred lines in carrots as the initial step in genetic analysis was begun at Davis, Calif., for the purpose of general genetic analysis, variety improvement, and increase of carotene content. The attempt to increase carotene content in the carrot is important, because it is a rich source of vitamin A, so necessary in the correction and prevention of certain nutritional disorders. Betacarotene and vitamin A appear to produce identical physiological effects. The general genetic analysis includes the following studies: Branched roots, cracked roots, root shape; wild *v.* cultivated root type; three different leaf colors; two flower colors; purple central flower *v.* normal; red, white, yellow, purple, and orange root colors.

At the outset it was observed that inbreeding reduced plant vigor, but the extent of reduction was difficult to learn, because some carrot varieties are genetically fast growing while some are slow growing. A barrier to studying the effect of inbreeding on carotene content was encountered in the difficulty of securing representative carotene samples from individual roots. Carotene is not uniformly distributed throughout the root, but apparently is first deposited at the top of the phloem zone, whence it gradually diffuses to the bottom of the phloem, and then to the top and bottom of the xylem core. After many trials it was learned that the most reliable index of carotene content was a colorimetric reading of the total extracted pigment before separation of carotene and xanthophyll. The correlation between the color reading and milligrams of carotene per 100 g of dry matter is very high. Since the pigment is fairly easily extracted, but the carotene determination is made only with much labor, the method is a valuable aid to carrot breeding for increase of carotene (*6*).

Studies on average root weight of inbred lines, and of hybrids among them, show that the numerous growth factors are segregated to the various lines in a manner corresponding to that for inbred

maize lines. Furthermore, the crossing of enfeebled inbred carrot lines gives the same manifestation of hybrid vigor as in F_1 hybrids of maize inbred lines. Presumably the hypotheses developed for size and weight inheritance in maize are applicable also to carrots, and we may expect important contributions from carrot genetics to the solution of the exceedingly difficult problem of size inheritance. An illustration of production of F_1 generations with excessive hybrid vigor is shown in the following cross between two inbred carrot lines at Davis, Calif. (data unpublished):

Hybrid vigor in a carrot cross

[Average weight, in grams]

Parent lines, A, 34.28; B, 36.42.
Fourth-generation inbred, A, 12.85; B, 24.87.
F_1 hybrid, 80.5.

The variety was Danvers Half Long and parent lines A and B were from strains inbred one generation. A planting of the variety from noninbred seed grown and pulled at the same time had a mean weightof 75 g. Since carrots increase in weight as they grow, it is necessary to pull at the same time all roots that are to be compared.

Some work is being done in California on analysis of root color in carrots.[7] In the cross White Belgian × Yellow Belgian the F_1 generation showed plants with the following different phenotypes:

a. White xylem, lemon phloem, white skin.
b. Lemon xylem, white phloem, white skin.
c. "Ringing" of lemon and white, white skin.

In a cross between an Indian purple carrot (purple phloem) × Commercial Danvers Half Long (orange phloem), the F_1 showed varying degrees of purple.

From the foregoing analysis of Yellow Belgian and White Belgian it is probable that the picture of a simple monohybrid contrast given by Tschermak (*38*) is inadequate.

IMPROVEMENT OF SALAD CROPS

ROSS C. THOMPSON, Associate Horticulturist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

THE group of vegetables including lettuce, celery, endive, chicory, cress, parsley, and cornsalad, of which the leaves or stems, or both, are eaten raw, are classed as the salad crops. The production and consumption of these crops, especially lettuce and celery, has increased enormously since their importance as sources of vitamins has become more generally recognized.

The crops of this group are comparatively exacting in their cultural requirements; hence commercial production is limited to areas that, on account of certain environmental conditions, are especially suitable for them. Only the two most important salad crops, lettuce and celery, are grown in large quantity for market.

Most of the cultivated varieties of the salad plants have arisen by selection of individual plants by market and home gardeners. In many cases the parentage and origin are unknown. Only within recent years has an effort been made to improve these crops by scientific methods from stock of known worth.

The salad plants other than lettuce and celery will not be dealt with in the present discussion, as very little work of a scientific nature has been done with the minor crops of this group. The dearth of material on the genetics of the salad plants is no doubt in a large measure due to the difficulties involved in making controlled crosses in many of these species. These plants all produce small flowers that are difficult to handle in securing controlled crosses for genetic studies. Three of them, lettuce, chicory, and endive, are composites, the flowers of which it is difficult, if not impossible, to emasculate, and this makes controlled crossing for genetic studies especially difficult.

The drawings in figure 1 show the structure of a lettuce flower, which is typical of the small-flowered composites. Since the anthers dehisce, or shed pollen, before the stigma appears beyond the sheath, it is necessary to remove the pollen from the stigmas and styles in order to obtain hybrid seed from cross-pollination.

The method of removing the pollen by means of a fine stream of water, first described by Oliver (*4*),[1] is generally employed. By careful washing with water when the individual florets have reached the stage of development shown in figure 1, *D*, it is possible to remove the pollen from the stigmas of most of the florets within the head. By applying the desired pollen to heads depollinated with water, a high percentage of hybrid seed may be obtained from the 15 to 20 ovules within a flower head. A knowledge of the inheritance of a number of

[1] Italic numbers in parentheses refer to Literature Cited, p. 339.

characters that could be identified in the first generation would greatly simplify germ-plasm studies in this group of plants. Many problems in disease resistance and environmental adaptation in the salad crops are awaiting solution by geneticists and plant breeders, and there is need for extended research in this field. Although limited in extent as compared with that on some other crop plants, noteworthy work in practical plant breeding has been done in the salad group.

LETTUCE

Lettuce is the most important salad plant and one of the most important of the vegetable crops. The present commercial crop has

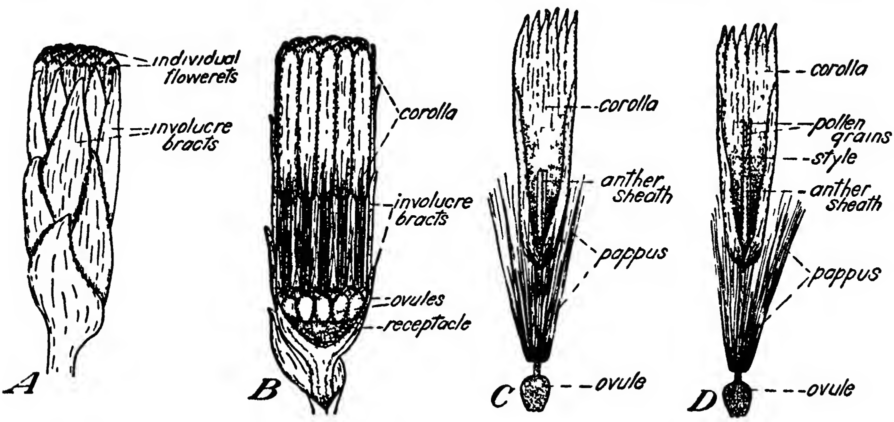

Figure 1.—*A*, The lettuce flower head a few hours before opening. *B*, A longitudinal section through a flower head just before opening, showing structure and arrangement of the individual florets within the involucre. *C*, An individual lettuce floret removed from the head, showing the floral organs. At this stage, a short time before full opening, the stigma is completely enclosed by the anther sheath. *D*, An individual lettuce floret a few minutes later than *C*. The rapidly elongating style has forced the stigma through the apex of the anther sheath. The anthers have already shed pollen, and some of the grains are lodged among the stylar bristles.

an annual value of about $28,000,000. Lettuce is in demand at all seasons of the year and is probably grown under more varied conditions in greenhouses and in field culture than any other vegetable.

Cultivated lettuce is known to botanists as *Lactuca sativa* L. This species has never been found in the wild state but is generally supposed to have been derived from the wild species *L. scariola* L., which is now widely disseminated and is a troublesome weed in many parts of the United States. Lettuce is native to India or central Asia. The time of its introduction into Europe is not known. It is one of the oldest of the vegetable crops. The records of Herodotus, Pliny, Hippocrates, and Aristotle indicate that it was grown as a garden plant in ancient times. It was reported in China as early as the fifth century A. D. Mention of it was made by Chaucer in England in 1340. It was introduced into America from Europe soon after the first colonies were established. Sixteen varieties were listed as being grown in American gardens in 1806.

Lettuce Types and Their Adaptation

Most horticulturists and seedsmen recognize four classes or types of lettuce, namely, crisp-head, distinguished by very firm heads of crisp texture; butter-head, distinguished by soft heads, the inner leaves of which feel oily to the touch; cos, distinguished by elongated heads, stiff leaves, and upright habit of growth; and loose-leaf or bunching, distinguished by loose, nonhead-forming leaves.

The crisp-head and butter-head types, which form round or flattened heads, are often spoken of collectively as "cabbage lettuces" to distinguish them from the "cos lettuces", which form elongated heads. Many good authorities consider that the cabbage and cos lettuces have been derived from two distinct botanical types. However, study of hybrid material from crosses between these two types indicates that they have a common origin.

Since lettuce is comparatively exacting in its environmental requirements during certain periods of its development, large-scale commercial production is limited to areas where climatic conditions are favorable during the critical growth periods. These are regions in which the mean temperatures are comparatively low during the heading period.

The commercial producing area of the United States can be roughly divided into three regions: (1) The western, including the Pacific Coast and Rocky Mountain States of California, Arizona, Colorado, Washington, Oregon, and Idaho; (2) the northeastern, including Massachusetts, New York, and New Jersey; and (3) the South Atlantic, which includes North Carolina, South Carolina, and Florida. On the basis of production the regions rank in the order named. The Western States produce approximately 85 percent of the entire crop.

The Western States grow largely the crisp-head type of lettuce, which sells on the eastern markets as "Western Iceberg." This term is confusing, as it does not refer to the Iceberg variety but applies to the numerous strains of crisp-head lettuce shipped to the markets from the West.

ONE *of the notable examples of practical plant breeding was the development of the Imperial strains of lettuce by the United States Department of Agriculture. Some years ago the lettuce industry in parts of the West, the Imperial Valley in particular, was threatened with ruin by the ravages of two diseases, brown blight and powdery mildew. The Imperial strains have remade the industry in these sections. They are resistant to both blight and mildew, and in certain lettuce-growing areas they now constitute 90 percent of the crop. In addition to their resistance to disease, each strain shows special adaptation to definite regional and climatic conditions.*

Formerly the western crop consisted almost entirely of strains of the variety New York or Wonderful. Much of the acreage formerly planted to this variety is now devoted to the disease-resistant Imperial strains.

Until recently the eastern lettuce crop consisted almost entirely of the butter-head varieties Big Boston and White Boston, also known as Unrivaled. In New York, New Jersey, and the Carolinas the butter-head varieties are being rapidly replaced by strains of crisp-head New York and the Imperials.

There would no doubt have been a more complete change from butter-head to crisp-head type in the East except for the fact that the California strains of crisp-head lettuce have not proved to be adapted to most parts of the East.

This shift from butter-head varieties such as Big Boston to the harder head type of lettuce has resulted from consumer demand. The consuming public has come to prefer the crisp-textured lettuce, and jobbers and dealers find that it stands handling and shipment better than the more delicate butter-head varieties. It has become difficult for eastern growers to find a market for the Big Boston type when the market can be supplied with the crisp New York or Wonderful type.

Cos or romaine lettuce has never been popular in America, although it has long been prized by European gardeners and is grown in home gardens in this country to some extent. There is a limited market for this type of lettuce among the foreign population of the larger cities. Although cos lettuce is coarse in texture, the best varieties are of high edible quality, lacking the bitterness so often present in other types, especially in some of the crisp-head varieties.

The production of loose-leaf or bunching lettuce is largely confined to the home garden and to greenhouse culture during the winter months, when there is considerable demand for this type of lettuce in some localities.

Greenhouse production of lettuce, which at one time constituted an industry of considerable importance, has declined rapidly as field production in the South and West has expanded. Fresh field-grown lettuce can now be obtained at all seasons of the year. A considerable quantity of lettuce is grown under glass during the winter months in the sections around the southern shores of the Great Lakes and near Boston, Mass. The leaf variety Grand Rapids is the most important variety around Cleveland, Ohio. The butter-head variety Belmay is the leading sort in the Boston section.

History of the Important Lettuce Varieties

When Tracy (*6*) published his descriptions of American varieties of lettuce in 1904, more than 100 distinct varieties were recognized. Since that time numerous new names have been added to the list.

Until the recent introduction of disease-resistant strains, to be discussed later, the commercial lettuce crop in the United States consisted largely of two or three varieties. Most of the lettuce reaching the markets from the West consisted of the crisp-head variety New York or Wonderful. The eastern crop consisted largely of the butter-head varieties Big Boston and White Boston.

138904°—37——22

Crisp-Head Varieties

New York or Wonderful is a very large, dark-green, solid, late, crisp-head variety. It is the most widely used of all lettuces and has been used as a parent in many of the recently developed strains. The variety was first named and introduced by Peter Henderson & Co. in 1896. Its parentage is unknown.

New York No. 12 is an early strain of a lighter color than the standard variety. It has been one of the most widely adapted crisp-head strains in the East. It was developed by pure-line selection from New York and introduced by the Pieters-Wheeler Seed Co.

New York Special No. 41 is a strain of the New York variety introduced in 1927 by the Ferry-Morse Seed Co., of San Francisco, Calif. It was obtained by pure-line selection from the New York variety. It is especially adapted to conditions in the Imperial Valley.

Imperial F is one of the best of the strains of the New York type resistant to brown blight and mildew. It was developed by Ivan C. Jagger, of the United States Department of Agriculture, from a cross of New York by a cos variety. It was released in 1930. Imperial F is now an important variety in parts of the West where brown blight and powdery mildew are prevalent.

Imperial 615 is a crisp-head lettuce resistant to brown blight, developed by Ivan C. Jagger from a cross between New York and a cos variety. It was first introduced in 1934 and has met with general favor.

Imperial No. 250 was introduced in 1929 by the Ferry-Morse Seed Co. It was obtained by pure-line selection from Jagger's Imperial No. 3. It is a uniform, widely adapted, disease-resistant strain of Imperial.

Hanson is a yellow-green crisp-head variety, a reliable cabbage-heading sort, apparently introduced by the Henry A. Dreer Co., of Philadelphia, Pa., about 1875. Its parentage is unknown.

Mignonette is a dark-green, reddish-brown, crisp-head variety of high quality but too small for a general market lettuce; it is of unknown origin and was first named and introduced in 1895 by Peter Henderson & Co.

The Iceberg variety (which should not be confused with the New York variety, often marketed as Western Iceberg), is a slightly pigmented, yellow-green, crisp-head variety. It is one of the most reliable of the crisp-head types for summer. Iceberg was introduced from Europe and named by W. Atlee Burpee & Co., of Philadelphia, Pa., about 1894.

Malta or Drumhead is one of the largest of all lettuce varieties. It is a coarse, light-green, crisp-head variety forming a loose head, of unknown foreign origin, introduced about 1850.

Denver Market is a very light green crisp-head variety first introduced by F. Barteldes & Co., of Lawrence, Kans., in 1890. Its popularity has been limited to the Middle West.

Butter-Head Varieties

Big Boston is the leading butter-head variety. It is grown in Europe as Trocadero. It has glossy, entire-margined leaves tinged with reddish brown. Its parentage is unknown, but it was first

named and introduced by Peter Henderson & Co. in 1890. Until recently Big Boston was the leading variety in the East.

The variety White Boston or Unrivaled may be described as Big Boston lacking the tinge of red anthocyanin pigment and having slightly lighter green leaves. It was first introduced in this country in 1902. It is believed to be identical with the variety listed by Vilmorin-Andrieux & Cie., of Paris, France, as Sans Rival.

White Boston Cornell No. 43 is a large dark-green strain of White Boston developed by the New York College of Agriculture. It seems to be well adapted for conditions in New York State.

The variety Salamander or Black-Seeded Tennis Ball is one of the most popular of the butter-head varieties. It is one of the oldest varieties of lettuce grown in this country. Its parentage is unknown, but it was introduced from Europe about 1856.

Deacon, one of the older of the American varieties of lettuce of the butter-head type, is distinguishable by its peculiar light gray-green color and its very spreading habit of growth. The variety was named and introduced by the Joseph Harris Co., of Coldwater, N. Y., in 1879.

Wayahead, a more recent addition to the list of lettuce varieties, is a small, early, bright-green, butter-head variety said to thrive under extremely adverse conditions. It was named and introduced by the W. Atlee Burpee Co., of Philadelphia, Pa., in 1908.

Belmay is the leading greenhouse variety in the Boston area. It is a downy mildew-resistant butter-head variety carrying a tinge of reddish brown. It was developed by the Massachusetts Agricultural Experiment Station from a cross between May King and the old reliable forcing variety, Hittinger Belmont. It was introduced in 1928. The variety is discussed later in this article.

Loose-Leaf or Bunching Varieties

Grand Rapids is the most popular of the so-called loose-leaf or nonheading type. It is quite hardy and well adapted for greenhouse culture, but not so well suited for growing out of doors. Grand Rapids was originated and named by Eugene Davis, a market gardener of Grand Rapids, Mich. It resulted from selection from the variety Black-Seeded Simpson. The variety was first introduced into the seed trade in 1890 by D. M. Ferry & Co., of Detroit, Mich.

Early Curled Simpson is a curly, yellow-green, nonheading variety, one of the best of the nonheading sorts for out-of-door culture. It is supposed to have originated about 1865 with a market gardener named Simpson, near Brooklyn, N. Y.

Black-Seeded Simpson is a nonheading variety similar to Early Curled Simpson, but larger and lighter green. Peter Henderson & Co. are said to have introduced the variety about 1880.

Prize Head is probably the best of the loose-leaf or nonheading varieties as regards quality, but is not liked by many on account of its reddish color, which develops especially during cool weather. Its origin is unknown, but apparently it was named and introduced by D. M. Ferry & Co., of Detroit, Mich., about 1868.

Cos or Romaine Varieties

Paris White Cos is the most popular of the cos or romaine type. As a salad lettuce for the home garden it has no superior. It is among the older varieties grown in this country, having been introduced from Europe about 75 years ago, and is considered to be a good variety for warm weather.

Dark Green Cos is similar to Paris White except that the leaves are a darker green. Its parentage and origin are unknown.

Lettuce Breeding

The different producing regions have had their specific problems for the plant breeder. The lettuce industry in some parts of the West, the Imperial Valley of California in particular, was at one time

Figure 2.—**Lettuce plants bagged to prevent uncontrolled pollination. Breeding plots in the Imperial Valley, Calif. Palm trees in middle distance.**

threatened with ruin by the ravages of two diseases, brown blight and powdery mildew. A notable example of practical plant breeding is the development of the mildew and brown blight resistant Imperial strains of lettuce by Ivan C. Jagger, of the United States Department of Agriculture, cooperating with the California growers and shippers. These strains have remade the industry in some sections of the West. They are of the general type of the popular and widely grown variety New York or Wonderful, and in addition to their resistance to disease, each shows special adaptation to certain regional and climatic conditions in the West. The breeding work was started in 1923 at Chula Vista, Calif. A lettuce-breeding plot in the Imperial Valley is illustrated in figure 2.

The strains resistant to both mildew and brown blight were given a letter in addition to the name Imperial. Jagger's other strains have been identified by numbers. The first brown blight-resistant strains released were obtained by selection from the variety New York.

The mildew-resistant strains were obtained by selection from material resulting from crosses between the New York variety and European varieties found by severe tests to be resistant to mildew. In some of the most important lettuce-growing sections of California, these strains now constitute 90 percent of the crop.

Imperial F has already been described. Imperial 13, introduced in 1932, was selected from hybrid material from a cross of New York with the French variety White Chavigne. Imperial 152 and Imperial 615, introduced in 1934, and Imperial 847, released in 1936, were all derived from a cross between New York and a cos variety.

One of the serious problems of eastern lettuce growers is the lack of crisp-head varieties of the New York or Wonderful type that will thrive under eastern soil and climatic conditions. The lack of varieties adapted for the East is explained by the fact that California not only grows more of the commercial lettuce crop than any other State but produces almost the entire seed supply for the United States. This concentration of the production of lettuce seed in California has resulted in the building up, through a long period of selection, of seed stocks especially adapted to western conditions but not to other sections of the country. Western crisp-head varieties almost always fail when tested in the East.

Breeding investigations for the purpose of developing strains of head lettuce of the New York type adapted for eastern conditions was begun by the writer in 1928. The work was begun at the Arlington Experiment Farm, Arlington, Va., and was moved to the United States Horticultural Station at the National Agricultural Research Center, Beltsville, Md., in the spring of 1935. The first strain resulting from this project was released under the name of Columbia No. 1 in the spring of 1936. A similar but earlier strain was introduced in the fall of 1936 as Columbia No. 2. These two varieties were selected from material obtained from a cross made in 1928 between the varieties New York and Hanson. Their chief merit is their adaptability to soil and climatic conditions in some parts of the East.

A third strain introduced in the fall of 1936 as Cosberg is a distinctly new type of head lettuce resulting from a cross of the varieties Iceberg and Paris White Cos. Trial tests of Cosberg show it to be capable of producing solid heads comparatively free of tipburn under conditions that result in severe tipburn in most varieties that will head at a high temperature.

As the breeding work at the Arlington Experiment Farm and the United States Horticultural Station has progressed it has become increasingly evident that the wide range of soils and climate existing in the producing centers of the East will require the development of strains especially adapted to local conditions. For example, it is evident that strains adapted for the muck soils of northern New York State are not likely to prove suitable for the soil and climate of the Carolinas, and that strains adapted for the lettuce section of Florida are not likely to meet the needs of growers in Massachusetts.

Within the last 2 years the Division of Fruit and Vegetable Crops and Diseases, in cooperation with the State experiment stations in New York, Massachusetts, New Jersey, and North Carolina, has undertaken the development of lettuce strains of the crisp-head type

adapted for the particular conditions prevailing in these different sections. The plan is to make available to the State experiment stations the breeding stocks developed at the United States Horticultural Station. In this way it is believed that the large amount of hybrid material now on hand can be used more effectively in securing strains to meet the needs of the several lettuce-growing centers in the East.

Plant breeders are becoming more conscious of the importance of local adaptation of varieties in their crop-improvement work. The needs of widely separated production centers cannot be met by one or two strains of a variety. No one strain is so cosmopolitan that it can adjust itself to such extremes of soil and climate.

Growers of greenhouse lettuce also have problems that have required the attention of the breeder. One of these is the loss from tipburn. This is a physiological break-down of the tissues at the margins of the actively growing leaves. The first appearance of the trouble is characterized by a breaking down of the marginal tissue between the larger veins. The affected area becomes somewhat transparent, loses its green color, and finally becomes brown or blackish. The disease is widespread, occurring wherever lettuce is grown, both under greenhouse and field culture, but it is usually most destructive in greenhouses. It is most likely to appear if high temperature prevails when the plant is in an active stage of growth and especially at the time the plant nears maturity. Much loss is caused by infection of the tipburned tissues by fungus diseases.

The Ohio Agricultural Experiment Station has contributed to the solution of this problem by the development of a strain of Grand Rapids lettuce resistant to tipburn. This is a dark-green, rapidly growing strain, selected from the standard leaf variety, Grand Rapids, and adapted for greenhouse culture.

One of the aims of the breeding work being carried on at the United States Horticultural Station by the Division of Fruit and Vegetable Crops and Diseases is the development of tipburn-resistant strains for field production. The Cosberg variety already released is a step toward the solution of this problem.

Mildew is also a serious problem in the production of lettuce under glass. It has been met by the downy mildew-resistant strain of Grand Rapids developed by Ivan C. Jagger in California, and by the powdery mildew-resistant variety Belmay developed by the Massachusetts Agricultural Experiment Station at Waltham, Mass.

The Jagger strain of Grand Rapids, developed from a cross between Grand Rapids and a cos variety, is a heavier, stalkier strain than the standard variety. It was released in 1936 as Grand Rapids U. S. No. 1.

Belmay is a butter-head type of lettuce adapted for greenhouse forcing. This is a mildew-resistant variety developed by selection from material obtained from a cross between the May King and the old reliable forcing variety Hittinger Belmont, or Hothouse. The cross and preliminary selection work was done by V. A. Tiedjens while he was a member of the staff of the Massachusetts Agricultural Field Station at Waltham. Its resistance to powdery mildew and its adaptation for forcing has made it the leading variety for greenhouse production in the Boston area.

CELERY

Celery ranks next to lettuce in importance as a salad crop. It was one time considered a luxury but is now a common item in the diet of many people.

The production of celery has increased rapidly during the last 10 years. The commercial crop now has an annual value of about $15,000,000. California, Florida, Michigan, New York, New Jersey, Colorado, and Oregon produce almost the entire celery crop of the country.

Celery (*Apium graveolens* L.) is a biennial plant native to the low marshlands of southern Europe, northern Africa, and southwestern Asia. A wild form is native in the southwestern United States. Although the plant was known to ancient peoples, recorded history indicates that it was not used as an article of food until modern times. Its development as a garden plant began among the gardeners on the lowlands of Italy and spread to France and England. By selection the undesirable wild plant, long considered poisonous, has been transformed into a crisp, sweet, appetizing, and wholesome item of food.

The commercial producing areas are even more limited than in the case of lettuce. The production of the early yellow type of celery is centered in the Sacramento district of California, the Sanford district of Florida, and the Kalamazoo district of Michigan.

Winter or green celery is produced in the market-garden sections around Great Salt Lake, Utah, Denver, Colo., Boston, Mass., and the trucking sections of New York, New Jersey, Michigan, and Pennsylvania.

History of Celery Varieties

There are two distinct types of celery—(1) yellow or summer celery, of which the variety Golden Self-Blanching is typical, characterized by its early maturity and ease of blanching, and (2) green or winter celery, of which Giant Pascal is typical, maturing later and having greater weight and better quality than the early yellow type. The yellow type can be blanched in the field as it stands in the row by excluding light merely by means of paper or boards. The green or winter varieties are more difficult to blanch. The plants must be either banked with soil as they stand in the row so that only the tips of the leaves are exposed to light or they must be dug and placed in light-proof pits to destroy the green coloring of the petioles.

Most of the old standard celery varieties—such as Golden Self-Blanching, Giant Pascal, White Plume, and Winter Queen—are of unknown parentage and origin.

Yellow Varieties

Golden Self-Blanching is one of the oldest of the yellow celery varieties. It has long been a standard variety in France and was very likely introduced to the United States from Europe. Its parentage is unknown. For many years French-grown seed of this variety was considered to be superior to American-grown stocks. Good strains of American-grown seed are now available. There are both tall and dwarf strains of this popular variety.

Easy-Blanching is a tall yellow celery resembling Golden Self-Blanching but a little later in maturing and having bright rich green

foliage. It is claimed that Easy-Blanching is hardier and more resistant to blight than Golden Self-Blanching.

White Plume is the earliest and most easily blanched of all celery varieties. The blanched petioles are snowy white. Most strains of this variety have the weakness of not keeping well after digging.

Golden Plume is one of the best of the early varieties. It is somewhat resistant to blight and keeps well in storage. The plants are medium in size, compact, and stocky. It is earlier, stalkier, and more vigorous than Golden Self-Blanching.

Some of the more recently developed yellow varieties include the yellows-resistant Michigan Golden and Curly Leaf Easy-Blanching, introduced by the Michigan Agricultural Experiment Station in 1933 and 1936, respectively; Non-Bolting Golden Plume, Golden Pascal, Crispheart, and Golden Supreme, developed and introduced by the Ferry-Morse Seed Co.

Green Varieties

Giant Pascal is one of the oldest of the green varieties. It is considered the standard of excellence in celery. The plants are tall and have rich dark-green foliage. The large thick petioles when blanched in soil are tender and crisp and have a rich nutty flavor. It is probably of European origin.

Winter Queen is a dark-green dwarf celery resembling Golden Self-Blanching in habit of growth. It matures earlier and is more easily blanched than Giant Pascal. It is probably an American variety, although its parentage is not known.

Fordhook is one of the best of the winter celery varieties, having good keeping qualities. The plants are somewhat dwarf in habit of growth, and the petioles are thick and heavy. It was named and introduced by the W. Atlee Burpee Co., of Philadelphia, Pa., in 1915.

A recent addition to the list of green varieties of celery is Utah. This is a strain of winter celery developed by the Chinese gardeners around the Great Salt Lake in Utah. The strain has also been called Chinese celery. It is a green celery of high quality, a week to 10 days later than Giant Pascal. The variety seems to be well adapted for some of the irrigated sections of the West.

Recent Celery Improvement

Celery growers look to the plant breeder for the solution of some of their most serious problems. Among these are the celery yellows disease, premature seedstalk development, pithiness, and obtaining earlier maturity.

Some of these problems have already been attacked by plant breeders and much has been accomplished in reducing losses.

Celery yellows first became a serious disease in Michigan. It was first observed there in 1914 and has since been found in Ohio, Pennsylvania, New York, New Jersey, Massachusetts, and Connecticut. Only the yellow celery varieties are susceptible, the green varieties being immune. Plants having the disease lose their normal color and become stunted; the tissues are brittle and have a bitter taste. The disease is caused by a species of *Fusarium* which remains in the soil and gradually becomes more abundant as celery is grown on the same land year after year.

The first attempt to solve the yellows problem by breeding methods was initiated by G. H. Coons and Ray Nelson, of the Michigan Agricultural Experiment Station. The work was later carried on by Ray Nelson and L. C. Cochran. The first strains released were resistant to yellows but were found to be too green to blanch easily. In 1933 the Michigan Golden Yellows Resistant strain was introduced. It was obtained by selection of yellows-resistant plants from a tall strain of Golden Self-Blanching.

The Michigan station has also introduced a yellows-resistant selection from the Newark Market variety. It was released in 1936 as Curly Leaf Easy-Blanching.

Some strains of celery shoot to seed prematurely if the plants are subjected to low temperature during the early growth period. In seasons when cold weather prevails after the plants have been set in the field or in cases where the seedlings in the plant-growing beds are subjected to low temperature, a heavy loss results from premature seeding. Emsweller (*3*) demonstrated the possibility of avoiding this trouble by breeding nonbolting strains.

The new Non-Bolting Golden Plume variety, developed by the Ferry-Morse Seed Co., and introduced in 1936, is a step toward the solution of this problem. The new strain was obtained by pure-line selection from the variety White Plume. The chief merit of the strain is its resistance to premature seedstalk formation under conditions that induce early seeding in many of the commercial varieties of early celery.

Pithiness in celery, a condition in which the parenchyma cells collapse, resulting in hollow, spongy petioles or stalks, has been shown by Emsweller (*2*) to be an inherited character. The establishment of the genetic basis of pithiness paves the way for the development by scientific breeding of strains free from this undesirable character.

The superior quality of green celery of the Giant Pascal type has long been recognized. On the other hand, the early yellow celery has the distinct advantage of being much more easily blanched than the green type. A celery combining the high quality and heavier stalks of the green celery with the early maturity and easy blanching characters of the yellow type would be a worth-while breeding accomplishment. The Ferry-Morse Seed Co. claim to have approached this in their new strain of Golden Pascal. It is a dark-green selection from Golden Plume.

The New York State College of Agriculture has investigations on celery breeding and genetics in progress but has as yet released no new strains.

GENETICS OF SALAD CROP PLANTS [2]

VERY little is yet known of the inheritance of characters in the salad crop plants. Some investigations have been made on the inheritance of certain characters in lettuce and in celery, but the genetics of only a few of these is known as yet.

[2] This section is written primarily for students and others professionally interested in breeding or genetics.

Lettuce

The most comprehensive study of the germ plasm of a salad crop plant is that made on lettuce by Durst (*1*). His investigations included the inheritance of plant height, time required for flower production, habit of growth, anthocyanin in the leaves and ray flowers, prickles on stems and leaves, seed color, leaf length, leaf width, and leaf area. Both cultivated varieties of *Lactuca sativa* and the wild form, *L. scariola*, were used in his studies.

Durst found anthocyanin in the leaves and ray flowers to be inherited as a single factor dominant to the absence of the pigment. Black seed behaved as if inherted via a single factor dominant to white seed. Prickles on the midrib of the leaves and on the stems are also inherited as a single factor dominant to the absence of prickles.

The inheritance of lobed leaves characteristic of some forms of the wild species *Lactuca scariola* is apparently controlled by complementary factors. The F_2 progenies from crosses of lobed with entire-margined leaf types gave approximately nine lobed to seven entire-margined.

Leaf length, leaf width, leaf area, time required for flower production, plant height, and habit of growth behaved as quantitative characters, and their inheritance is controlled by many factors.

Thompson [3] has determined the inheritance of certain color characters in lettuce. A report is made on the inheritance of three distinguishable anthocyanin pigment types in the leaves, of dark-green and yellow-green chlorophyll color, of seed color, and of a chlorophyll deficiency that does not follow Mendelian inheritance.

The three anthocyanin pigment types in the leaves of lettuce studied by Thompson were the full red type characteristic of the variety Mignonette, the spotted type characteristic of the variety California Cream Butter, and the tinged type characteristic of the variety Iceberg.

The inheritance of these three anthocyanin types was found to be controlled by a multiple allelomorphic series of three genes and two pairs of complementary genes. The presence or absence of the pigment is controlled by the complementary genes and the intensity and pattern by the multiple allelomorphic series.

Dark-green chlorophyll color, characteristic of the variety New York, was found to behave as a single factor dominant to the gene for yellow-green characteristic of the variety Hanson.

Studies on seed color confirm the results obtained by Durst that black seed is due to a single gene dominant to the gene for white seed.

The chlorophyll deficiency in the leaves of lettuce studied by Thompson was found to be non-Mendelian in inheritance. The deficiency was inherited only through the deficient portions of the mother plant,and its inheritance was not affected by the type of pollen applied.

Celery

The inheritance of pithiness in celery has been studied by Emsweller (*2*) in the variety Utah. Emsweller isolated inbred lines from this variety that were homozygous for solid petioles free from pithiness.

[3] Thompson, R. C. Genetic relations of some color factors in lettuce (In manuscript; intended for publication as U S. Dept. Agr. Tech Bull)

Progenies from heterozygous lines segregated approximately three pithy to one nonpithy. The results obtained indicate that pithiness in celery is controlled by a single factor, dominant to the recessive condition of solid or nonpithy petioles.

It should be noted here that the problem of pithiness in celery was practically solved by Sandsten and White (*5*) in 1900. They observed that certain stocks of plants of the variety Golden Self-Blanching from different sources varied greatly in the percentage of pithy plants produced. Strains of both American- and French-grown stocks were tested. Lots from the French-grown seed showed much less pithiness on the average than lots from the American-grown seed. Some of the French stocks were entirely free of pithiness, which White and Sandsten, who reported the work, attributed to more careful selection of seed stocks by French growers. Although Sandsten and White's results strongly indicated an inherited difference in strains in respect to pithiness, they failed to carry their investigations far enough to show a definite genetic relationship.

Premature seedstalk development in celery has also been studied by Emsweller (*3*). The varieties Golden Plume and Golden Self-Blanching were used. Emsweller was able to isolate strains homozygous for the nonbolting habit, which would not bolt under conditions causing a high percentage of bolting in other strains. He was able to isolate some lines that were strongly annual in their seeding habit, some plants of which seed prematurely even under favorable conditions for vegetative growth. It is evident from his results that premature seedstalk development in celery is inherited. He concluded that nonbolting is a quantitative recessive character. The influence of environment on the expression of the bolting character makes genetic analysis of it difficult.

IMPROVEMENT OF VEGETABLE CROPS—APPENDIX

VICTOR R. BOSWELL, Principal Horticulturist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry, from survey data submitted by domestic and foreign investigators

THE appendix to these articles on vegetable improvement consists of four tabulations of information as follows:

1. A list of vegetable varieties developed by State and Federal research agencies and released by them for commercial use.

2. A list of vegetable strains, varieties, and breeding stocks or groups of the same that are in the hands of State and Federal research workers and which have some special merit, or are of practical or theoretical interest as breeding material. It should be noted that material listed in table 1 is not repeated in table 2, although practically without exception introducers of varieties all maintain some stock of their introductions. Table 2 should properly include all material listed in table 1.

3. A list of vegetable breeding and improvement activities in the United States by States and crops.

4. A brief summary of vegetable breeding and improvement activities in countries other than the United States.

The data in these tabulations and summaries were obtained through a questionnaire sent to all vegetable crop research agencies in this country and to a large number in other lands. The writers of the present articles are grateful for the generous help of their fellow workers, both here and abroad, in making this compilation possible. Despite the great amount of data submitted and the generous response to our requests, it is known that these appended tables do not contain all of the data that could well be included. Some of the workers interrogated were perhaps too modest to list certain cultures as being important or of interest to others; others were admittedly too pressed by other matters to prepare a detailed list of their material and activities. But even though the data are incomplete, the reader will find clues to nearly every kind of vegetable-breeding material that is available and leads to the numerous investigators who are engaged with the hundreds of breeding and improvement problems that are receiving attention today.

The writers hoped that it would be possible to include similar tables of information relating to private work by commercial seedsmen. The immensity of the task of determining the origin of the hundreds of varieties made it impossible. A few commercial firms keep rather complete records of the parentage and dates of their introductions, but most do not. The major role that has been played by private agencies has been repeatedly referred to in these articles, and acknowledgment made to individuals and firms wherever pertinent information could be included. It should thus be clear to all that no discrimination is intended by the omission of more extensive data on commercial contributions. Unfortunately, justice cannot be done to such a task within the space available here.

TOMATO—Continued

Station or U S Department of Agriculture	Crop	Variety name	Date introduced	Parents	Breeding method	Superior characters
Tennessee	Tomato	Tennessee Pink		Unknown	Mass selection	Fusarium wilt resistant
Department	do	Tennessee Red	1912	Beauty	do	Do
	do	Norton	1917	Stone	Selection	Do
	do	Marvel	1918	Merveille de Marchés	do	Fusarium wilt and nailhead resistant
	do	Columbia	1918	Greater Baltimore	do	Fusarium wilt resistant
	do	Arlington	1918	do	do	Do
	do	Norduke	1922	Norton × Duke of York	Hybridization	Do
	do	Marvana	1924	Marvel × Earliana	do	Do
	do	Marvelosa	1924	Marvel × Ponderosa	do	Fusarium wilt and nailhead resistant
	do	Marglobe	1925	Globe × Marvel	do	Do
	do	Break o' Day	1931	Marglobe × Marvana	do	Do
	do	Pritchard [2]	1932	Cooper Special × Marglobe	do	Resistant to fusarium wilt, nailhead, and cracking
	do	Glovel [2]	1935	Globe × Marvel		
Washington	do	Seedling No 36	1930	Bonny Best × Best of All	Hybridization	Heavier producer than parents Good shipper
	do	Seedling No 50		do	do	Heavier producer than parents

CUCURBITS

Station or U S Department of Agriculture	Crop	Variety name	Date introduced	Parents	Breeding method	Superior characters
California	Watermelon	California Klondike	1933	Klondike	Inbreeding	Uniformity, flesh color, edible quality
	do	Long Mountain	1936	Stone Mountain	do	Oblong type, adapted to shipping
	do	Striped Klondike	1936	Striped Klondike	do	Uniformity, high sugar
	do	Resistant Klondike No 7	1936	Iowa Belle × Klondike	Hybridization	Wilt resistant
	Bush squash	Grey Zucchini No 1	1936	Zucchini	Inbreeding	Early, productive small, single-stem plant
	Cantaloup [3]	Powdery Mildew Resistant Cantaloup No 1	1931 1931	Resistant variety from India and several commercial varieties	Hybridization	Resistant to powdery mildew
	do	Powdery Mildew Resistant Cantaloup No 50	1932	do	do	Do
	do	Powdery Mildew Resistant Cantaloup No 50-15	1933	do	do	Do
	do	Powdery Mildew Resistant Cantaloup No 45	1935	Hale Best × unfixed variety from India	do	Resistant to powdery mildew edible quality Superior shipping qualities
	Honey Dew melon	Powdery Mildew Resistant Honey Dew No 60	1934	Unfixed variety from India × Honey Dew × Honey Ball	do	Resistant to powdery mildew, edible quality

Connecticut (State)	Squash	Connecticut Straight Neck	1936	Straight Neck Inbred × Giant Summer Crook Neck	do	Early, productive, uniform, smooth
Florida	do	African	1935		Introduction	High quality and yield in Florida, some resistance to stem borers
	Watermelon	Leesburg	1936	Kleckley Sweet	Pure line selection on wilt infested soil	Resistant to fusarium wilt in Florida
Iowa	do	Iowa King	1930	Conqueror × (²)	Hybridization	Resistant to fusarium wilt
	do	Iowa Belle	1930	Conqueror × Kleckley Sweet	do	Do
	do	Pride of Muscatine	1930	Kleckley Sweet	Selection	Do
	Squash	Des Moines		Des Moines	Inbreeding	Uniformity and quality
Maryland	Muskmelon	Maryland Gem	1928	Buskirk s Gem	Selection	Thick, yellow flesh quality
Michigan	Cucumber, pickling	National Pickle	1929	Snow Pickling	Single plant selection massing of selfed lines	High yield, superior pickling quality
Minnesota	Squash	Kitchenette	1930	Green Hubbard	Inbreeding	Uniformity family size
	do	New Brighton	1932	do	do	Uniformity large size
	do	1 35	1935	Buttercup	do	Early high quality, family size, stores well
	Cucumber	454 35	1935		Introduction and inbreeding	Early, productive pickling type
	Watermelon	Northern Sweet	1932		do	Early, high quality, productive
New York (State)	Cucumber	Geneva	19[illegible]	Arlington White Spine × Rochford Market	Hybridization	Parthenocarpic
North Dakota	Squash	Buttercup		Quality × Essex hybrid (²) (natural cross)	Inbreeding	Convenient size, high quality, easily prepared
Department	Cantaloup [4]					
	Watermelon	Conqueror	1911	Eden × Stock citron	Hybridization	Resistant to fusarium wilt
Vermont	Squash	Vermont Hubbard		Hubbard	Inbreeding	Improved uniformity and culinary quality

SWEET CORN

Connecticut (State)	Sweet corn	Spancross C2	1933	Spanish Gold × C2	Hybridization	First early hybrid, large ear resistant to bacterial wilt
	do	Spancross P39	1933	Spanish Gold × P39	do	Second early resistant, good quality
	do	Marcross C6	1933	G E Market × C6	do	Very large ear, first early, resistant
	do	Marcross C13 6	1935	C13 × C6	do	Do
	do	Marcross C13 2	1935	C13 × C2	do	Do
	do	Marcross P39	1935	G E Market × P39	do	Second early, very large ear, good quality resistant
	do	Whipcross C6 2	1933	C6 × C2	do	Midseason, large ear, resistant
	do	Whipcross C7 2	1933	C7 × C2	do	Midseason, large ear, narrow kernel, quality
	do	Whipcross P39 C2	1933	P39 × C2	do	Midseason, large ear, resistant to bacterial wilt
	do	Whipcross P39	1933	Whipple × P39	do	Midseason large ear, good quality, resistant
	do	Redgreen	1926	C78 × C77	do	White, good quality, sun red leaves
	do	M Spanish Gold	1935	Spanish Gold	Synthetic variety	Very early, parent of first early hybrid
	do	M G E Market	1935	G E Market	do	Early, resistant to bacterial wilt
	do	M Whipple	1935	Whipple	do	Midseason, resistant to bacterial wilt

TABLE 4.—*Improved varieties and strains of vegetable crops, peanuts, and sweet corn developed and released by State and Federal research agencies*—Con.

SWEET CORN—Continued

Station or U S Department of Agriculture	Crop	Variety name	Date introduced	Parents	Breeding method	Superior characters
Florida	Sweet corn	Florida No 191	1934	Country Gentleman, Cuban Flint, Loveless, Pope and Stubbs	Hybridization inbreeding bulk crossing of inbreds and selection	Husk protection and good table quality
	do	Suwannee Sugar	1935	Southern Snowflake ¾, Long Island Beauty ¼	Hybridization and one back cross to Snowflake, selection	Husk protection, southern plant type, good quality
Illinois	do	Illinois Narrow Grain Evergreen				
	do	Inbred No 13	1935	Narrow Grain Evergreen	Best open pollinated strains first selected by ear row methods, followed by inbreeding and a high degree of selection within each line, then tested out in numerous crosses	Cross 14×13 is a high yielder available commercially in 1937
	do	Inbred No 14	1935	do	do	Do.
	do	Country Gentleman	1925	Country Gentleman	Ear row selection	Yield, uniformity, canning quality, adaptability to Illinois
	do	Narrow Grain Evergreen	[5]1925	Narrow Grain	do	Do
	do	Illinois Country Gentleman	1935	Country Gentleman	Same as for Illinois Narrow Grain inbreds	Yield, uniformity, canning quality, adaptability to specific Illinois conditions
	do	Inbred No 1	1935	do		Do
	do	Inbred No 3	1935	do		Do
	do	Inbred No 5	1935	do		Do
	do	Inbred No 6	1935	do		Do
	do	Inbred No 8	1935	do		Do
	do	Inbred No 9	1935	do		Do
	do	Inbred No 10	1935	do		Do
	do	Inbred No 15	1935	do		Do
	do	9 hybrids		do	Same as for Illinois Narrow Grain inbreds	Do
Maryland.	do	Hopeland	1920	Stowell Evergreen × Johnson County White	Hybridization	Productivity
North Dakota	do	Sunshine	1924	Golden Bantam × Gill s Early Market	Hybridization, selfing, followed by selection and close breeding but not selfed	Earliness, size, quality
	do	Golden Gem	1928	Sunshine × Pickaninny	do	Extreme earliness and quality.
	Popcorn	Pinkie	1935	Black Beauty × Jap Hulless	Hybridization and selection	Novelty.

Texas	Sweet corn	Surcropper Sugar	1933	Country Gentleman × Surcropper.	Crossing and backcrossing repeatedly to field corn parent.	Earworm resistant, adapted to certain southern conditions.
	do	Honey June	1933	Country Gentleman × Mexican June.	do	Do.
Department (in cooperation with Indiana station.	do	Golden Cross Bantam	1932	Purdue 39 × Purdue 51	Hybridization	High yield, excellent quality, resistant to bacterial wilt, uniformity of type and maturity, high production of stover.
Department (in cooperation with Puerto Rico).	do	U. S. D. A. 34	1937	Native field corn and sweet mutation of native sweet corn.	Alternate generations of selfing and backcrossing on native field corn. The final crossing was a double-top cross between 2 second-generation inbred lines and 2 ear-to-row selections.	Resistant to corn stripe. Thick, tightly clasping husks. Vigorous plant, size similar to field corn. Large ears with kernels of unusual depth.
				MISCELLANEOUS CROPS		
Ohio	Beet	Ohio Canner	1932	Detroit Dark Red	Inbreeding and sib-mating	Dark color, round shape, absence of light rings.
Massachusetts	Carrot	Hutchinson	1923	Hutchinson	Mass selection	Long, smooth root; high yield.
California	Onion	California Early Red, U. C. No. 1.	1935	California Early Red	Inbreeding	Uniform size, shape, color, time of maturity, keeping quality.
	do	Australian Brown, U. C. No. 1.	1935	Australian Brown	Inbreeding, massing large numbers of similar unrelated lines.	Flesh color, scale color, keeping quality, fertility.
Colorado	do	Sweet Spanish, Colorado Station No. 6.	1936	Sweet Spanish	Inbreeding	Yield uniformity; better storage; improved color.
Texas	Peanut	McSpan	1925	Little Spanish	Pure-line selection	High yield, early maturity, high oil content.
Virginia (in cooperation with Department).	do	Experiment Station Jumbo.	1935	Jumbo	Selection	Very large pods and nuts; hard hulls.
Department	do	Spanish 18-38.	1925	Red Spanish.	do	Superior yielding capacity.
Connecticut (State)	Pepper	Windsor A	1936	California Wonder × Bountiful.	Hybridization	Early, productive; thick wall.
Louisiana	do	Baton Rouge Cayenne.	1934	Best local stocks of Red Cayenne.	Inbreeding	Size, uniformity, color, pungency and yield.
	do	C-2811 (not yet named)	1936	Baton Rouge Cayenne	Inbreeding and selection	Earliness, pungency; yield; resistant to defoliation by *Cercospora capsici*.
	do	Sport	1936	Native Sport × Honka (Japanese variety).	F_1 backcrossed to Honka to intensify red color.	Uniformity; productivity and superior color.
	do	T-10-1 (Tabasco)	1935	Best local stocks of Tabasco	Inbreeding	Uniformity; productivity; color; ease of harvesting.
	do	T-10-2 (Tabasco)	1935	do	do	Uniformity; fruit color and wall thickness; ease of harvesting.
Massachusetts	do	Waltham Beauty	1935	Unknown	Selection	Thick fruit; early; high yield.
New Mexico	do	Chile No. 9	1917	Mexican Chile	do	Improved adaptability, uniformity

[5] Released first to Illinois Canners Association in 1933 and to seedsmen in 1935.

TABLE 4.—*Improved varieties and strains of vegetable crops, peanuts, and sweet corn developed and released by State and Federal research agencies*—Con

MISCELLANEOUS CROPS—Continued

Station or U S Department of Agriculture	Crop	Variety name	Date introduced	Parents	Breeding method	Superior characters
Louisiana	Shallot	Unnamed	1936	2 local varieties	Crossing and selecting desirable F_1 plants	Resistance to pink root, fast growing, vigorous plants
	Sweetpotato	Porto Rico	1935	Porto Rico	Hill unit selection	Sprouts earlier, produces more plants per unit and 20 percent higher yield than parent stock
	do	Porto Blanco	1935	do	Mutation	White skin, white flesh, high yield high in starch ideally suited for starch manufacture, and for livestock feed
North Carolina	do	Porto Rico N C No 1	1928	do	Hill and tuber selection	High yield, smooth skin, uniform color uniform appearance
Department	do	Mameyita	1919	Unknown	Introduced from Puerto Rico	High quality, good keeper and yielder
	do	Japanese Yam	1930	do	Introduced from Japan	High starch content, resistant to *Fusarium batatatis* and *F hyperoxysporum*
	do	Oebi aboelan	1926	do	Introduced from Java	High quality and marked resistance to *F batatatis*
	do	Kloranda Dutch Yellow	1930	do	do	Do
Puerto Rico	Eggplant	Puerto Rican Beauty	1936	A 4 × University	Hybridization	Highly resistant to bacterial wilt

TABLE 5.—*Outstanding vegetable strains, varieties, and breeding lines of practical or theoretical interest that are in the cultures of State and Federal research agencies*

BEAN

Station or U.S Department of Agriculture	Crop or type	Variety name or no	Date obtained or started	How obtained	Parents	Characters of interest
Idaho	Canning	W-80	1934	Hybridization	Corbett Refugee × Stringless Refugee	Resistant to common bean mosaic, high productivity
	Garden	White Wax No 122	1935	do	Brittle Wax × White Refugee Wax	White seeded wax bean of Kidney Wax type
	do	Wax No 110	1935	do	Hybrid Wax U S No 536 × Corbett Refugee	A Refugee type wax bean resistant to common bean mosaic
	Semifield	Burtners Blight Proof	1934	Introduced by Mr Burtner, of Wasco County, Oreg	Not known	Resistant to curly top

Illinois	Lima	Henderson Bush 11 lines	(1)	Selection and crossing	Henderson Bush	Uniformity
	do	Wood s Prolific 4 lines	(1)	Selection	Wood s Prolific	Under test in 1936 for commercial value
	do	Baby Potato Lima, 6 lines	(1)	do	Henderson Bush	Henderson Bush vine and earliness, with small thick potato type beans crowded in pods Outyields Henderson
	do	Large Podded Henderson Bush 9 lines	( )	Cross between two selections	do	Large podded early, productive under Illinois conditions
Iowa	Green	Wholegreen		Hybridization	Burpee Stringless Green Pod × Refugee	Straight, stringless pods
			1930	do	Brittle Wax × unnamed	Attractive pod color
Minnesota	White pod	Fusduli	1932	Introduced	Unknown	Seed characters
New York (Cornell)			1915 to date	Numerous unnamed seedling	Hybrids of and selections from Robust, Wells Red Kidney, White Marrow Flat Marrow Scotia and White Imperial	Variously resistant to root rot, blight immune to mosaic and to specific strains of anthracnose
Department (in cooperation with Oregon)		About 100 lines	1928 to 1933	Hybridization	Resistant × susceptible varieties	Curly top resistance
		Corbett Refugee	1931	Selection from Sioux City Seed Co	Stringless Green Refugee	Mosaic resistant
Department (in cooperation with Colorado)		N 1092	1935	Hybridization	Brittle Wax × Corbett Refugee	Excellent wax bean type, good color and excellent pods
		N 675	1933	do	Pinto × Cranberry Striped Creaseback	Tolerant to bacterial blight
		Numerous other lines	Mostly since 1930	Hybridization and selection	American and foreign varieties	Disease resistance and adaptation possibilities

LEAFY CROPS

Arizona	Lettuce	Imperial No 152	In process	Selfing individual heads and roguing the increase	Imperial 152	Improved adaptation to Arizona conditions and conformity to varietal type
	do	Imperial No 615	do	do	Imperial 615	Do
Colorado	Lettuce head			Crossing	New York No 12 × Iceberg	Improvement in resistance to tipburn
Florida	Lettuce	1	1934	Selection	New York	Appears to show superior ability to develop hard head under certain growing conditions
	do	6	1934	do	do	Do
	do	15	1934	do	do	Do
	do	26	1934	do	do	Do
Hawaii	do	5 United States commercial varieties	1932	Introduced		Mignonette is good parent because of excellent heading under warm conditions Hybrids of California commercial varieties with Mignonette show promise

1 Started 1930 Best lines of 1936

Table 5.—*Outstanding vegetable strains, varieties, and breeding lines of practical or theoretical interest that are in the cultures of State and Federal research agencies*—Continued

LEAFY CROPS—Continued

Station or U S Department of Agriculture	Crop or type	Variety name or no	Date obtained or started	How obtained	Parents	Characters of interest
Minnesota	Brassica hybrids	1 35	1935	Hybridization	Brussels sprouts—cabbage hybrids	Gives promise of forming head and sprouts
	do	14-35	1935	do	do	Give promise of being an early type of brussels sprouts
	Crucifer hybrids	54 35 Fertile Hybrid	1930	do	Radish × cabbage	Generic hybrid of scientific interest May serve same purpose as rape
New York (Cornell)	Cabbage	Numerous strains	1919 to date		Homozygous for various factors and characters as purple, magenta sun color, and green, waxy dwarf types and others	Breeding stocks for practical or theoretical work
	do	Numerous lines	do		Intertype crosses of *Brassica oleracea* cabbage × cauliflower, brussels sprouts, kale, kohlrabi wild cabbage	For genetic study
	Celery			Hybridization	Golden Self Blanching × Utah	Self blanching, good quality, resistant to fusarium yellows
Department	Lettuce	4 lines	1929	do	Iceberg × Hanson	Heat resistant, reliable heading strains
	do	3 lines	1929	do	Mignonette × Hanson	High quality, early maturity
	do	7 lines	1929 and 1932	do	New York × Hanson	Solid, dark green, reliable heading types for eastern conditions
	do	MN 29-8-7	1929	do	Mignonette × New York	Tipburn and heat resistant
	do	P-1H-1190-3	1930	do	Two hybrid lines	Tipburn resistant
	do	IP-30-1 20	1930	do	Iceberg × Cos	Tipburn resistant, high edible quality
	do	MN-P-1193	1931	do	Two hybrid lines	Tipburn resistant, early maturity
	do	2 lines	1931	do	Imperial C × hybrid	Tipburn resistant
	do	2 lines C-NH-1 4	1931	do	do	Reliable heading
	do	6 lines	1931	do	Two hybrid lines	Tipburn resistant
	do	4 lines MN-NH-150	1932	do	do	Ability to head under adverse temperature conditions
	do	NT 12 1	1928	do	New York × Transport	Genetic material for chlorophyll deficiency
	do	BD-3 1	1928	do	California Cream Butter × Deacon	Genetic material for inheritance of Cos type
	(2)					
	do	M		Selection	Mignonette	Red *CCRRTT*
	do	B		do	California Cream Butter	Spotted *CCr'r'TT*
	do	I		do	Iceberg	Tinged *CCrrTT*
	do	H		do	Hanson	Green *CCRRtt*

	do	N		do	New York	Green $ccrrTT$
	do	T		do	Transport	Green $CCr'r'tt$
	do	C		do	Chavigne	Green $CCrrtt$
	do	NC		Hybridization	New York × Chavigne	Green $ccrrtt$
	do	MN		do	Mignonette × New York	Green $ccRRTT$
Department (in co-operation with Wisconsin)	Cabbage	77 lines homozygous for resistance to yellows	1930	Pure-line selection	Smith Pride variety	Useful for outcrossing to individuals selected for resistance
			PEA			
Maryland	Many lines		Mostly since 1928	Hybridization and pure lining	Commercial varieties	Wilt resistant
Department (in cooperation with California)	Progress type [3]	-	1932	Hybridization and selection	Laxton Progress × Giant Stride	Resistance to *Fusarium orthoceras pisi* Tolerance to unnamed Fusaria found at San Luis Obispo
	Hundredfold type [3]		1932	do	do	
	do	N762 and others	Mostly since 1932	Hybridization	do	Resistant to *Fusarium* tolerant to *Ascochyta*
	do	15 strains	do	do	Little Marvel × World Record F_4	Resistant to certain viruses Freezing types seed setting
	do	6 strains	do	do	Laxton Progress × Nain Mangetout F_4	Size of pod, hardiness
	do	132 strains	do	do	Laxton Progress × Giant Stride F_5–F_8	Resistant to fusarium wilts
	do	4 strains	do	do	Laxton Progress × World Record	Pod size seed setting
	do	30 strains	do	do	Laxton Progress × Kent Alderman	Pod size hardiness
	do	15 strains	do	do	Laxton Marvel × (Thomas Laxton × Phenomenon)	Resistant to certain viruses freezing types seed set resistant to fusarium wilts
	do		do	do	Austrian Winter × Alderman	Genetics and breeding for resistance to *Ascochyta* and *Mycosphaerella*
	do		do	do	Austrian Winter × Hundredfold	Do
	do		do	do	Austrian Winter × Perfection	Do
	do		do	do	Little Marvel × Progress F_1–F_3	Resistant to certain viruses
	Pisum elatius	2 strains	do	do		Not fully explored
	P jomardi	3 strains	do	do		Do
	Subspecies of *P sativum*	5 strains	do	do		Do
	Edible-podded	19 strains	do	do		Do
	Pure lines and varieties	300 strains	do	do		Do

[2] Homozygous genotypes for anthocyanin pigment in leaves of lettuce maintained at the Beltsville station
[3] It is planned to release these as soon as increased sufficiently

TABLE 5.—*Outstanding vegetable strains, varieties, and breeding lines of practical or theoretical interest that are in the cultures of State and Federal research agencies*—Continued

TOMATO, EGGPLANT AND PEPPER

Station or U. S. Department of Agriculture	Crop or type	Variety name or no.	Date obtained or started	How obtained	Parents	Characters of interest
California	Tomato	Many hybrids	1936	Hybridization	Red Currant × commercial varieties	Resistant to bacterial canker and spotted wilt
	do	Many varieties	1936	Inbreeding	Commercial stocks	Uniform type for variety
Georgia	Pepper	Pimiento	1928	Line selected	Perfection Pimiento	
	Tomato	Livingston Globe	1920	do	Livingston Globe	Resistant to wilt
	do	7-1-1	1926	Hybrid line selected for resistance to wilt and leaf diseases	Globe × Burpee	Resistant to wilt, heat, and drought
	do	22-3-1	1932	Above backcrossed to wilt resistant strain of Globe	(Globe × Burpee) × Globe	Do
	do	2-3-1-1	1932	Hybridization	Globe selection × Break o' Day	Resistant to wilt
Iowa	do	79		Crossing	Farliana × Best of All	Less cracking
Hawaii	do	Hawaii station hybrid	1918	Horticulture department	Obscure. Hybrid between a wild currant type and a commercial variety	Shows partial resistance to melon fly (*Bactrocera cucurbitae*) but has small size
	do	United States commercial varieties	1932–35	Introduced		
	do	2 local wild currant tomatoes				
Maryland	do	Strain of Red River No. 44-9	1930	Selection	Red River	Early; resistant to cracking
Minnesota	do	Various strains	1930–33	Breeding introduced	Numerous	Early; productive
Missouri	do	*Lycopersicon pimpinellifolium* × *L. esculentum* hybrids	1935	Hybridization	*Lycopersicon pimpinellifolium* × *L. esculentum*	Studies of fusarium wilt resistance and inheritance of resistance
New Hampshire	do	Bonny Best	------	Selection	Bonny Best	Strain adapted for forcing
	Eggplant	Unnamed	------	Dwarf Purple × Black Beauty	Hybridization	Earliness; adaptability to Northern States
New Jersey	Tomato [4]	Marglobe × J. T. D. crosses	------	Crossing and selection	Marglobe × J. T. D.	Undergoing selection for improved yield, fruit shape, color, and general high quality
	do	Break o' Day × Oxheart crosses		do	Break o' Day × Oxheart	Do
	do	Marglobe × Earliana crosses		do	Marglobe × Earliana	Being selected for larger, smoother, high-quality, early market tomato

Tennessee	do	Usual commercial varieties.				
Texas	do	B-1	1935	Hybridization	Large Cherry × Bonny Best.	Sets fruit under unfavorable conditions; prolific.
	do	377	1935	do	Gulf State Market × Cherry.	Sets fruit under unfavorable conditions; prolific; free from "puff."
Department.	do	50 Marglobe lines	1932	Inbreeding	Marglobe	Wilt-resistance studies.
	do	50 lines	1925–35	Hybridization	Marglobe and other commercial sorts.	Being tested prior to release of best; wilt and nailhead resistant.
	do	125 varieties	1932	Inbreeding	European varieties	For disease-resistance and inheritance work.
	do	130 varieties	1932	do	American varieties	Do.
	do	100 varieties	1935–36	Introduction	Australian, South American, and Asiatic sources.	Do.
	do	Numerous lines	1935	Hybridization and backcrossing.	*Lycopersicon pimpinellifolium* × *L. esculentum* and reciprocals.	Do.
Wyoming	do	Denmark	1932	Denmark		Desirable type and fruiting habit.
	do	Bonny Best	1930	U. S. Department of Agriculture.		High quality.
	do	Bison	1932	North Dakota Agricultural College.		Early.
	do	Yellow Pear	1930	U. S. Department of Agriculture.		Do.
	do	Currant	1930	do		Do.
Puerto Rico.	Eggplant	A-4	1930	Hybridization	Black Beauty × Fajardo	Resistant to bacterial wilt.

CUCURBITS

Arizona	Cantaloup	McDaniels Nugget	In process	Selfing individual plants and rigidly roguing each strain.	McDaniels Nugget	Uniform size, globe shape, deep flesh, salmon color, deep net, high sugar.
	do	Superfecto	do	do	Superfecto	Do.
California	Muskmelon	Hale Best	1926–36	Inbreeding; 10–15 inbred lines being carried along.	Commercial stocks	Uniformity of plant and fruit characters.
	do	Salmon Tint	1926–36	do	do	Do.
	do	Honey Dew	1926–36	do	do	Do.
	do	Honey Ball	1926–36	do	do	Do.
	do	Persian	1926–36	do	do	Do.
	do	Casaba	1926–36	do	do	Do.
	do	Many minor horticultural varieties and subspecies.	1926–36	One or more inbred lines		
	Squash	White Bush Scallop	1930–36	10–15 inbred lines of each	Commercial stocks	Uniformity of fruit and plant characters.
	do	Giant Summer Crookneck.	1930–36	do	do	Do.
	do	Giant Summer Straightneck.	1930–36	do	do	Do.

[4]Other crosses: Marglobe × Stone, Argentina × Gulf State Market, Shanghai × Marvel, Cooper × J. T. D., Peiping × J. T. D , Pritchard × J. T. D., and others.

Table 5.—*Outstanding vegetable strains, varieties, and breeding lines of practical or theoretical interest that are in the cultures of State and Federal research agencies*—Continued

	do	Long Mountain No. 216	1936	do	do	Do
	do	Northern Sweet No. 251	1936	do	do	Do
	do	Sun Moon Stars No. 265	1936	do	do	Do
	do	Grey Monarch No. 260	1936	do	do	Do
	do	Iowa Belle No. 542	1936	Hybridization	Unknown	Uniform fruit type for variety, resistant to wilt
	do	Pride of Muscatine No. 136	1936	Inbreeding		Do
	do	Hybrid No. 7	1936	Hybridization	Klondike × Iowa Belle	Klondike type, resistant to wilt
	do	Hybrid No. 19	1936	do	do	Kleckley type, resistant to wilt
	do	Hybrid No. 16	1936	Inbreeding		Klondike type, resistant to wilt
Florida	Cantaloup	Rocky Dew	1935	From Kilgore Seed Co.	Rocky Dew	Resistant to mildew and certain leaf spots
	Squash	African	1933	Plant Exploration and Introduction, U. S. Department of Agriculture	African squash	Superior eating quality and yielding ability, considerable resistance to stem borer
	Watermelon	Iowa Belle	1931	Introduced from Iowa		Shows some resistance to wilt under Florida conditions
	do	Iowa King	1931	do		Do
Iowa	Squash	Improved Table Queen		Inbreeding	Isolation of high yielding inbred lines	Increased uniformity and yield and freedom from mixtures

Louisiana	do	Sugar Bowl		Crossing and backcrossing	Scalloped White Bush × Des Moines.	Very uniform; deep teacup shape; white color; very fleshy; sweet; high quality.
Maine	Cucumber	Line 155	1932	Selfing	Windermoor Wonder	Resistant to scab (*Cladosporium cucumerinum*).
	do	Line 128	1932	do	Longfellow	Do.
Massachusetts	Squash	Blue Hubbard No. 1		Selfed pure line	Commercial Blue Hubbard.	Uniform fruit; high yield; good color; strain lacks roughness desired by growers.
Michigan	Muskmelon	Honey Rock inbreds	1935	Inbreeding	Honey Rock	Some lines for hard shell and ropy net.
	do	$3=S_5$; $2=S_6$		do		Some lines for thick flesh and high total solids.
	do	1730 F_3	1935	Hybridization	Hale Best × Honey Rock	Thick flesh of Hales and shell and net of Honey Rock (not fixed as yet).
	do	1731 F_2	1935	do	(Hale Best × Honey Rock) × Honey Rock.	More characters of recurrent parent.
	do	1739 F_5	1935	do	Honey Dew × Emerald Gem.	Orange flesh of Emerald Gem; shell of Honey Dew.
	do	4 F_3 lines	1937	do	Honey Dew × Champlain on Hearts of Gold.	Early maturing; green flesh. Honey Dew.
Minnesota	Cucumber	Numerous strains	1914-36	Introduction; selection. inbreeding. hybridization.	Many varieties	Pure lines for several genetic characters.
	Muskmelon	do	1932	Selection	Golden Osage	Resistant to fusarium wilt.
	Watermelon	do	1931	Hybridization	Arikara, Northern Sweet, Fordhook, Angelino, Winter Queen.	Early; seed color; quality.
	Squash	do	1920 36	Introduction; selection; inbreeding, hybridization	Many varieties	Pure lines for several genetic characters.
New Hampshire	Cucumber	Granite State	25-30 years ago	Hybridization	English × White Spine	Excellent forcing cucumber; thirfty grower; prolific.
New York (Geneva)	Squash	*Cucurbita moschata* × *pepo* 31.	1933	do	Japanese Pie × Early Yellow Bush Scallop.	Potential disease resistance.
	do	*Cucurbita moschata* × *pepo* 32.	1933	do	Japanese Pie × Mammoth Yellow Bush Scallop.	Do.
	do	*Cucurbita pepo* × *moschata* 43.	1933	do	Giant Summer Crookneck × Japanese Pie.	Do.
	do	*Cucurbita moschata* × *maxima* 52.	1933	do	Quaker Pie × Banana	Do.
	do	*Cucurbita moschata* × *pepo* 64.	1933	do	Japanese Pie × Delicata	Do.
	do	*Cucurbita pepo* × *moschata* 70.	1934	do	Bohemian (=Delicata) × Japanese Pie.	Do.
Department (in cooperation with California).	Muskmelon	Numerous lines		do	American and oriental sorts.	Powdery mildew resistance.

TABLE 5.—*Outstanding vegetable strains, varieties, and breeding lines of practical or theoretical interest that are in the cultures of State and Federal research agencies*—Continued

CUCURBITS—Continued

Station or U S Department of Agriculture	Crop or type	Variety name or no	Date obtained or started	How obtained	Parents	Characters of interest
Department at Beltsville, Md	Cucumber	40 lines	Mostly since 1930	Inbreeding	Japanese and Chinese varieties	Some resistance to mosaic
	do	50 lines		Hybridization	American × Japanese or Chinese varieties and reciprocals	Do
	do	10 lines		Inbreeding	American and oriental varieties	Some resistance to bacterial wilt
	do	20 lines		Hybridization	do	Do
	do	6 lines		Inbreeding	Chinese and Indian varieties	Some resistance to downy mildew
	do	5 lines		Hybridization	Chinese × American varieties	Do
Department at Corvallis, Oreg	Squash	Several lines	1932	Inbreeding	Marblehead	Uniform productive, resistant to curly top
	do	do	1933	Hybridization	Marblehead × Beau Dessert	High quality adapted to Northwest
	do	do	1932	Inbreeding	Varieties of *Cucurbita pepo*	Potential disease resistance
Department at Cheyenne, Wyo	Muskmelon	Griffin	1934	Canada		Early maturity
	do	John the Gardener	1934	Wyoming gardener		Early maturity and quality
	do	Vine Peach	1935	Commercial		Tartness of flavor early maturity
	do	Hale Best	1935	do		High quality
	Squash and pumpkin	New England Pie	1930	do		Early, and good quality
	do	Cocozelle	1930	do		Bush habit of growth
	do	Giant Summer Crookneck	1930	do		Bush habit of growth early,
Puerto Rico	Cucumber	Chinese Long	1933	Introduction		Resistant to downy mildew
	do	35-2 8-3 2	1935	Hybridization	Chinese Long × Early Black Diamond	Do

SWEET CORN

California	Sweet corn	Papago	1934	Associated Seed Growers, Inc.	Commercial stocks	Earworm resistant.
	do	Honey June	1934	Texas Agricultural Experiment Station.		Earworm and heat resistant.
	do	California No. 1	1935	Hybridization	(Honey June × Oregon Evergreen) × Honey June.	Earworm resistant.
	do	California No. 2	1935	do	(Honey June × Oregon Evergreen) × Oregon Evergreen.	Do.
	do	California No. 3	1935	do	(Honey June × Golden Bantam) × Honey June	Do.
	do	Surcropper Sugar	1934	Texas Agricultural Experiment Station		Do.
	do	Florida 191	1934	Florida Agricultural Experiment Station.		Do.
	do	Oregon Evergreen	1934	F. Lagomarsino.	Commercial stock	Do.
	Dent corn	Mexican June	1934	Aggeler & Musser	do	Earworm and heat resistant.
	do	King Philip	1935	F. Lagomarsino	do	Earworm resistant; yellow kernels.
	do	Davis Prolific	1935	Reuter Seed Co.	do	Earworm resistant.
	do	Tuxpan	1935	Texas Agricultural Experiment Station.		Do.
Connecticut (State)	Sweet corn	Connecticut 2	1933	Inbreeding	Whipple	Dark green foliage, vigorous plant, narrow kernel.
	do	Connecticut 6	1933	do	do	Light green foliage, resistant to bacterial wilt, broad kernel.
	do	Connecticut 7	1933	do	do	Narrow kernel, good plant and ear.
	do	Connecticut 13	1935	do	Golden Early Market	Very resistant to bacterial wilt. Golden Early type of ear.
	do	Connecticut 78	1926	do	Red leaves (probably from Crosby).	Good quality.
	do	Connecticut 77	1926	do	Stowell Evergreen.	Large ear, good quality, pearly white.
	do	P 39			(?)	Good quality; adaptability; resistant.
	do	P 51			Golden Bantam	Good quality; 8-rowed ear.
Florida	do	Sweet Snowflake	1934	Recurrent backcrossing	Snowflake, Long Island Beauty.	Husk protection, southern type.
	do	Alachua Sweet	1935	do	White Dent, Long Island Beauty.	Do.
	do	Sweet Dubose	1935	do	Dubose, Long Island Beauty.	Do.
	do	Sweet Tuxpan	1935	do	Tuxpan, Florida 191	Husk protection; adapted to Everglades.
	do	Sweet Oklahoma Silvermine.	1935	do	Oklahoma Silvermine, Suwannee Sugar.	Husk protection, southern type.
	do	Sweet Trucker Favorite	1935	do	Trucker Favorite, Suwannee Sugar.	Husk protection, southern type; earliness.

TABLE 5.—*Outstanding vegetable strains, varieties, and breeding lines of practical or theoretical interest that are in the cultures of State and Federal research agencies*—Continued

SWEET CORN—Continued

Station or U. S. Department of Agriculture	Crop or type	Variety name or no.	Date obtained or started	How obtained	Parents	Characters of interest
Florida	Sweet corn	Florida King Bantam	1935	Recurrent backcrossing	Hickory King, Cuban Flint, Suwannee Sugar.	Husk protection, southern type, Golden Bantam ear type, tender and very good quality.
Illinois	do	22-507-806-4-104-203	( )		Iowa State College No. 15 Evergreen × Yellow Dent.	(6).

	do	5068-8-1 1 276			do	
	do	5068-8-1 3-278			do	
	do	9 hybrids	1935	Hybridization	Narrow Grain Evergreen × Country Gentleman	Superior yield
Indiana (in cooperation with Department)	do	G B 14	1921	Pure line selection	Golden Rod	Excellent pollinator few suckers good quality
	do	G B 51B	1922	do	Golden Bantam	Carries factor for high yield, tall, slender plant Good pollen parent
	do	C G 22	1921 [7]	do	Country Gentleman	Resistant to kernel infection Produces an early top cross with open pollinated strains Two ear type
	do	C G 34	1931	do	do	Carries factor for kernel depth
	do	C G 6355	1928	do	do	Stiff stalk root rot resistant
	do	S F 4-6	1921	do	Stowell Evergreen	Productive good seed quality
	do	S F V4	1928	do	do	Productive root rot resistant
	do	N G 119	1921	do	Narrow Grain Evergreen	Deep, narrow kernel erect resistant to ear rots
	do	N G 1014 2 5	1921	do	do	Good root system, slender ear
Iowa	do	Iogold 18 39		Crossing of inbred lines	Sunshine inbreds	Increased yield and uniformity
	do	Iogent 16 45 Iogent 90 45		do	Country Gentleman inbreds	Do
	do	Iogreen 123 91 Iogreen 11 63		do	Narrow Grain Evergreen inbreds	Do

[5] Work started in 1929 and the lines listed are those showing merit as of 1935

[6] These lines are all inbreds the number of generations inbred being indicated by the number of integers in the pedigree A great many additional inbreds are being maintained (142 inbred lines in all) but only those showing distinct merit are listed The object is to secure single crosses able to withstand the heat and drought of central Illinois and to show a high degree of resistance to bacterial wilt Purdue Golden Cross Bantam is not sufficiently resistant to wilt for the purpose All the lines listed show promise They range all the way from extremely early 8 row to late maturing 18 row types

[7] First year of inbreeding

TABLE 5.—*Outstanding vegetable strains, varieties, and breeding lines of practical or theoretical interest that are in the cultures of State and Federal research agencies*—Continued.

SWEET CORN—Continued

Station or U. S. Department of Agriculture	Crop or type	Variety name or no.	Date obtained or started	How obtained	Parents	Characters of interest
Maryland	Sweet corn	About 50 inbreds	Mostly since 1930.	Hybridizing sweet × dent corn followed by inbreeding. Own production.	Commercial varieties	Yield and adaptability.
	do	Many inbreds		Commercial and research agencies.		For comparison.
New York (State)	do	G5.	1927	Inbreeding	Golden Bantam	High quality; potent hybridizer.
Pennsylvania	do	Purdue 39	1936	From Glenn Smith, Lafayette, Ind.		
	do	Purdue 51	1936	do		
	do	Purdue 13391-8-1	1936	do		
	do	Purdue 1351-3-1-1-2.	1936	do		
	do	Purdue 3-1-3-2	1936	do		
	do	Purdue 1308	1936	do		
	do	Purdue 8482	1936	do		
	do	Purdue 14-1-2-6	1936	do		

MISCELLANEOUS CROPS

Station or U. S. Department of Agriculture	Crop or type	Variety name or no.	Date obtained or started	How obtained	Parents	Characters of interest
Minnesota	Asparagus	375 different plants, nos. 2-1 to 9-43.	1932	Selection	Washington	Production and breeding records known.
Department	Beet	Several lines	Mostly since 1930.	Highly uniform inbreds from commercial varieties.	Commercial varieties	Some commercial possibilities; others of genetic interest only.
Minnesota	Carrot	36-34, 37-34	1934	Selection and inbreeding	Chantenay	Uniform.
California	Garlic	Early or Mexican		Selection	Commercial stocks	
	do	Late or Italian		do	do	
	do	Many introductions			Through Plant Exploration and Introduction.	
Louisiana	Okra [a]					
California	Onion	Stockton Yellow Globe 36-40.		Selfed one generation	Stockton Yellow Globe (commercial stock).	Uniform; nonbolting.
	do	White Persian	1929	Plant Exploration and Introduction.	P. E. I. No. 86279	Thrips resistant.
	do	Stockton Yellow 21-1-3-4-S_4.		Inbreeding	Stockton Yellow (commercial).	Nonbolting.

	do	Italian Red 13–53		Selection	Italian Red (commercial)	Male sterile mildew resistant
	do	Lord Howe Island		Australia	Lord Howe Island	Deep red, early
	do	Australian Brown No 17		Inbreeding	Australian Brown	Resistant to pink root
	do	Sweet Spanish No 35		do	Sweet Spanish	Do
	do	Nebuka		Japan	Nebuka selection	Do
Louisiana	do	Creole		Inbreeding and selection followed by intercrossing similar lines and mass open pollination of similar lines (Stocks maintained at Louisiana)	Best local stocks	Excellent keeping quality, high total solids Very strong flavor, desired by certain markets and processors Adaptable to short-day growing conditions
Texas	do	White Persian	1935	California station		Disease resistant
	do	Crystal Wax	1935	Selection	Individual plants	Deep nonsplitting
Georgia	Peanut	Improved White Spanish	1931	Tom Huston Peanut Co		Small, uniform seed of high quality
	do	Pearl	1931	do		White seed coat poor quality
	do	Carolina Runner	1931	do		Resistant to disease high yield
	do	Virginia Runner	1931	do		Resistant to disease, large seed
	do	Virginia Bunch	1931	do		Bunch, large seed
	do	Jumbo	1931	do		Large seed fairly resistant to disease
	do	Tennessee Red	1931	do		Bunch, large pods suitable for roasting
	do	Basse	1931	do		Resistant to disease, well filled
	do	West African	1931	do		Resistant to disease
	do	Philippine White	1931	do		Resistant to disease, white seed
	do	Kimorales	1931	do		Bunch, fairly resistant to disease
	do	Java P I	1931	do		Bunch said to be resistant to bacterial wilt
	do	H13–36–66	1934	Selected hybrid	Pearl × Carolina Runner	Resistant to disease fine hay
	do	H19–54 13–3	1935	do	Improved White Spanish × Carolina Runner	Do
	do	H21 39–39	1934	do	Improved White Spanish × Virginia Runner	Do
Virginia (in cooperation with Department)	do	15 selections from Virginia Runner	1935	Selection	Virginia Runner	Large pods hard seed hulls and superior yields
Department (in cooperation with Virginia and South Carolina)	Peanut	About 250 varieties and introduction	Mostly since 1930	Mostly by introduction	Mostly through Plant Exploration and Introduction	Largely unexplored
Minnesota	Rhubarb	Various strains	1932 36	Inbreeding selection introduction	Several varieties	Improved color and quality
Hawaii	Sweetpotato	Black Spanish	1934	Introduced		
	do	Red Jersey	1922	do		
	do	Dixie Yam	1922	do		
	do	Jewel Yam	1922	do		
	do	Priestly	1934	do		
	do	Creola	1922	do		
	do	Pohrico	1934	do		

[a] Pure lines of the leading varieties are being maintained at the Louisiana station
[b] These selections have been placed in the hands of a selected group of growers for multiplication and distribution

TABLE 5.—*Outstanding vegetable strains, varieties, and breeding lines of practical or theoretical interest that are in the cultures of State and Federal research agencies*—Continued

MISCELLANEOUS CROPS—Continued

Station or U S Department of Agriculture	Crop or type	Variety name or no	Date obtained or started	How obtained	Parents	Characters of interest
Hawaii	Sweetpotato	Japanese Brown	1917–22	Introduced		
	do	Nancy Hall	1934	do		
	do	Vineless Yam	1934	do		
	do	Merced	1934	do		
	do	Madeira	1917	do		
	do	40 Hawaiian varieties	1917–35	Collected from various islands		
	do	20 hybrids	1926–29	Hand crosses of known varieties		
	do	40 open pollinated seedlings	1934	Seed collected in field open pollinated		Selection for eating quality is most important object
Maryland	do	Menes Moeder	1923	Introduction	Introduced from Java	High quality and marked resistance to *Fusarium batatatis*
Department	do	do	1923	do	do	High starch content Resistant to *Fusarium batatatis* and *F. hyper-oxysporum*
	do	254	1923	do	Big Wig × (?)	
	do	291	1923	do	do	
	do	About 25 varieties	Since 1919	From growers in United States	Unknown	Of commercial interest in past or at present
	do	About 30 numbers	Since 1919	Foreign introductions	do	Of potential commercial and breeding value Many are resistant to *Fusarium*
	do	About 100 seedlings	Since 193	Open pollinated seed	Female parent known	Do

Table 6.—*Recent vegetable breeding activities of State and Federal agencies in the United States*

[Parentheses enclose names of investigators no longer connected with the institution]

State or department and crop	Nature of studies	Personnel
Alabama:		
Vegetables	Searching the State for superior strains or plants	C. L. Isbell.
Arizona:		
Lettuce and cantaloup.	Selection within commercial varieties for local adaptation.	W. E. Bryan, M. F. Wharton.
California:		
Asparagus	Inheritance of spear size, shape, head tightness, toughness, node size.	(H. A. Jones, G. C. Hanna.)
Cantaloup (part in cooperation with Department).	Inheritance of fruit size and qualitative characters, resistance to powdery mildew. Effect of inbreeding.	(J. T. Rosa,[1] G. W. Scott), I. C. Jagger,[2] T. W. Whitaker.[2]
Celery	Inheritance of pithiness and bolting	(S. L. Emsweller.)
Onion	Inheritance of color of flesh, scale, foliage, seed; size of seed; bolting; sterility. Cytology of *Allium* species hybrids. Resistance to thrips.	(H. A. Jones, S. L. Emsweller)
Peas	(See Department cooperation with California)	
Squash (*Cucurbita pepo*).	Inheritance of fruit and plant characters and fruit size. Effect of inbreeding.	(G. W. Scott.)
Spinach	Inheritance of resistance to mosaic	Do.
Sweet corn	Determination of factors governing earworm resistance; nature of factor interaction in hybrid vigor by crossing inbred lines.	(C. F. Poole.)
Tomato	Inheritance of fruit size; resistance to spotted wilt and bacterial canker.	(O. H. Pearson), D. R. Porter.
Watermelon	Inheritance of color of flesh, rind, seed coat; sugar content, rind toughness; size of seed; resistance to wilt.	(J T. Rosa,[1] G.W. Scott), D. R. Porter (C. F. Poole).
Colorado:		
Bean (snap)	Breeding for mosaic resistance and adaptability to canning in Colorado.	A. M. Binkley.
Lettuce	Breeding for tipburn resistance by intervarietal crossing and selection.	Do
Onion	Inbreeding and selection in Sweet Spanish for improved market type and adaptability to Colorado.	Do
Connecticut:		
Bean (lima)	Selection for high yield	D. F. Jones, W. T. Singleton, L. C. Curtis.
Pepper	Inheritance of seedless character	Do.
Squash	Nature of hybrid vigor by crossing inbred lines.	Do.
Sweet corn	Development of early, disease-resistant, high quality, productive new varieties and hybrids for canning and market through use of inbreeding, hybridization, and production of "synthetic varieties." Inheritance of several seed, seedling, and plant characters, and study of zygotic and gametic lethals. Studies of hybrid vigor.	Do.
Delaware:		
Cabbage	Inheritance of qualitative characters	L. R. Detjen, E. W. Greve.
Florida:		
Sweet corn	Developing earworm-resistant sweet corn of good quality adapted to Florida by intervarietal crosses, backcrosses, and selection.	F. H. Hull, W. A. Carver.
Tomato	(See Department cooperation with Florida.)	
Watermelon	Selection for wilt resistance	M. N. Walker.
Georgia:		
Peanut	Inheritance of color of leaf and seed coat; growth habit; size and shape of seed and pods; size and shape of leaflets; resistance to cercospora leaf spots, *Sclerotium rolfsii* and physiological seed spot. Hybrid vigor.	N. C. Woodroof.
Tomato	Intervarietal crosses for wilt resistance and adaptation to Georgia conditions.	H. L. Cochran.
Hawaii:		
Lettuce	Hybridization and selection to obtain varieties that will head well at low altitude in the subtropics.	(C. P. Wilsie), J. H. Beaumont, M. Takahashi.
Sweetpotato	Controlled hybridization, selection, and use of open-pollinated seed to obtain high quality, yield, and if possible resistance to weevil.	Do.
Tomato	Intervarietal and species crosses and selection to obtain resistance to melon fly. Resistance to late blight and mosaic being sought.	Do.
Idaho:		
Bean	Development of improved disease-resistant varieties by intervarietal crossing and by pure-line selection. Inheritance of resistance to common bean mosaic.	W. H. Pierce, Leif Verner, G. W. Woodbury.

[1] Deceased.
[2] Of U. S. Department of Agriculture.

TABLE 6.—*Recent vegetable breeding activities of State and Federal agencies in the United States*—Continued

State or department and crop	Nature of studies	Personnel
Illinois:		
Bean (lima)	Intervarietal crosses and pure-line selection for improved yield and adaptability to Illinois conditions.	W. A. Huelson.
Sweet corn	Inheritance of rowing, nature of hybrid vigor in crosses of inbred lines. Production of high yield and quality sweet corn for Corn Belt conditions.	Do.
Tomato	Intervarietal crosses and selection for wilt resistance in field and greenhouse types and adaptation to high-nitrogen prairie soils.	Do.
Indiana:		
Tomato	Selection for wilt resistance and improved adaptability to Indiana conditions.	E. C. Stair, (J. H. MacGillivray).
Iowa:		
Bean (snap)	Intervarietal crossing and selection for high-quality beans adapted to Iowa.	A. T. Erwin, E. S. Haber.
Tomato	Intervarietal crossing and selection for high-quality tomatoes adapted to Iowa.	Do.
	Nature of inheritance of specific qualitative factors, determination of linkage relations, inducing and studying inheritance of new variants, study of polyploid forms and cytology thereof.	E. W. Lindstrom
Sweet corn	Improving yield and uniformity through crossing of inbreds developed from commercial varieties. Inheritance of resistance to drought and bacterial wilt.	A. T. Erwin, E. S. Haber.
Louisiana:		
Collard, carrot, okra, pepper.	Inbreeding and selection to obtain strains of superior market value and productivity adapted to Louisiana conditions.	J. C. Miller.
Cabbage, onion	Crossing of inbred lines to attain objectives stated above.	Do.
Shallot, squash, tomato.	Crossing and backcrossing commercial varieties to attain objectives stated above.	Do.
Sweetpotato	Hill unit selection and isolation of mutants to improve stocks and obtain new sorts of specific value as for starch manufacture.	
Maine:		
Bean	Selection, crossing, and backcrossing to improve Yellow Eye type; development of blight- and anthracnose-resistant sorts. Inheritance of eye pattern, color, vine characters, seed size, and linkage relations.	(F. M. Surface, K. Sax), H. C. McPhee, (F. V. Owen), I. M. Burgess, (C. R. Burnham), R. M. Bailey.
Cucumber	Inbreeding and selection for resistance to *Cladosporium cucumerinum*.	I. M. Burgess, R. M. Bailey
Tomato	Selection for earliness and resistance to cracking	R. M. Bailey.
Maryland:		
Cantaloup, sweetpotato.	Selection for quality, yield, and adaptation	T. H. White.
Pea	Selection for resistance to wilt	C. E. Temple.
Spinach	Mass selection for increased winter hardiness	(F. W. Geise, H. B. Cordner)
Sweet corn	Study of natural selection in successive generations of sweet × dent corn cross. Development of varieties and hybrid sweet corns from inbreds from sweet × dent crosses. Studies of hybridization technique.	W. B. Kemp, R. G. Rothgeb (A. Stabler).
Tomato	Hybridization and selection for quality, yield, and adaptation.	T. H. White, J. B. S. Norton.
	Early work on selection for disease resistance.	
Massachusetts:		
Asparagus	Selection and crossing selected plants to study transmission of yielding ability.	Robert E. Young.
Celery	Development of superior strains of Pascal through inbred selections.	Do.
Lettuce (cooperation with Department).	Hybridization and selection to obtain crisp heading varieties and greenhouse types for Massachusetts.	Do
Squash	Development of superior strain of Warted Blue Hubbard by inbred selections.	Do.
Tomato	Hybridizing *Lycopersicon pimpinellifolium* and *L esculentum* to obtain leaf mold resistance.	F. F. Guba.
Michigan:		
Beans	Crossing and backcrossing varieties to obtain higher quality, darker green, mosaic resistance, and better pod-setting in canning sorts.	C. H. Mahoney, H. L. Seaton, Ray Nelson, Miriam Strong.
Brussels sprouts	Inbred selections (greenhouse bud pollination) to develop strains for upland and for muck soils.	Do.

TABLE 6.—*Recent vegetable breeding activities of State and Federal agencies in the United States*—Continued

State or department and crop	Nature of studies	Personnel
Michigan—Continued.		
Celery	Inheritance of resistance to yellows	C. H. Mohony, H. L. Seaton, Ray Nelson, Miriam Strong.
Cucumber	Inbred selections for greater fruit length in National Pickle.	Do.
Muskmelon	Inheritance of netting and sterility. Honey Rock inbred selections for hard rind and ropy net; for thick flesh and high solids. Varietal crosses and backcrosses involving Hale Best, Honey Dew, Honey Rock, Emerald Gem, Champlain, and Hearts of Gold for improved quality, appearance, and adaptability of specific new combinations of characters.	Do.
Radish	Root selection for short top, uniformity, shape, and color in Scarlet Globe.	Do.
Sweet corn	Inbreeding, hybridization, and selection for resistance to European corn borer, tolerance to bacterial wilt, and high canning quality. Development of desirable inbred pollen parents.	Do.
Minnesota:		
Asparagus	Selection within Washington strains to improve yield and study transmission of yielding ability.	(R. Wellington, J. W. Bushnell, W. T. Tapley), F. A. Krantz, T. M. Currence, A. E. Hutchins, assisted by J. G. Leach, T. M. McCall, T. S. Weir, M. J. Thompson.
Bean	Inheritance of several qualitative and quantitative characters.	Do.
Brassica spp.	Genetic and cytological study of cabbage × radish and Brussels sprouts × cabbage hybrids.	Do.
Carrots	Selection of superior strains through inbreeding	Do.
Cucumber	Inheritance of a number of qualitative and quantitative characters including plant height, determinate growth, and study of shape correlations.	Do.
Cucurbits, other (muskmelon, squash, watermelon).	Varietal crosses and selection to develop fusarium wilt resistance. Inheritance of qualitative factors in squash.	Do.
Eggplant	Studies similar to those on cucumber	Do.
Pepper	Inheritance of several qualitative and quantitative characters, studies of shape correlations.	Do.
Rhubarb	Inbreeding, selection, hybridization for improving petiole color and quality.	Do.
Tomato	Inheritance of growth habit, time of ripening, fruit size. Effect of polyploidy on economic characters. Study of certain linkages.	Do.
New Hampshire:		
Eggplant	Varietal crosses and selection to obtain earlier sorts adapted to Northern States.	J. R. Hepler, G. F. Potter.
Tomato	Selection of locally adapted forcing strains. Study of hybrid vigor in intervarietal crosses.	Do.
New Jersey:		
Tomato	Varietal crosses, backcrosses and selection for improving yield, color, and wilt resistance of canning types.	L. G. Schermerhorn, C. M. Haensler.
New Mexico:		
Onion	Selection of Spanish types for improved quality and adaptability to the Southwest.	F. Garcia.
New York (Cornell):		
Bean (chiefly field types).	Hybridization of varieties followed by pedigreed selection for development of disease-resistant varieties. Inheritance of resistance to specific diseases. Minor attention to inheritance of other characters. (Early work on inheritance of qualitative and quantitative characters.)	W. H. Burkholder, R. A. Emerson, A. L. Harrison, D. Reddick. (M. F. Barrus, W. H. Burkholder, G. P. McRostie, R. A. Emerson).
Cabbage	Improving variety uniformity and quality by selection. Developing new and superior combinations of characters by hybridization and selection. Inheritance of color, stem length, head shape, texture, and flavor (odor). Intertype crosses involving cabbage, cauliflower, brussels sprouts, kale, kohlrabi, and wild cabbage for cytogenetic study.	C. H. Myers, W. I. Fisher.
Celery	Inheritance of color; size, shape, and toughness of petioles; resistance to yellows.	R. A. Emerson.
Lettuce (cooperation with Department).	Selection within hybrid progenies and varieties for improved heading, quality, and tipburn resistance.	J. E. Knott, (J. B. Hartmann.)

Table 6—*Recent vegetable breeding activities of State and Federal agencies in the United States*—Continued

State or department and crop	Nature of studies	Personnel
New York (Geneva)		
Bean (snap)	Varietal crosses to obtain mosaic resistant improved sorts Inheritance of mosaic resistance	A L Harrison, J G Horsfall
Cucumber	Varietal crosses to obtain improved greenhouse types	W T Tapley
Cucurbita spp	Interspecific hybrids among *C maxima*, *C pepo*, and *C moschata* to determine specific limitations within the genus and possibilities of developing new and valuable combinations of characters, including disease resistance Inheritance of mosaic resistance	G P Van Eseltine
Muskmelon	Hybridization to obtain earlier and higher quality varieties	W D Enzie
Pea	Inheritance of root rot resistance	A L Harrison, J G Horsfall
Squash	Hybridization to obtain earlier and higher quality varieties	W D Enzie
Sweet corn	Development of new inbreds for production of superior hybrid corns for canning and market Chemical studies of hybrids	P V Traphagen
Tomato	Selection and varietal crosses for improved canning varieties adapted to the Northeast	C B Sayre
North Carolina		
Lettuce (cooperation with Department)	Selection within hybrid progenies and varieties for improved heading quality, and tipburn resistance	Robert Schmidt
Sweetpotato	Hill unit selection for improvement of varietal type and yield	Do
Tomato	Hybridization and selection for resistance to bacterial wilt	Do
North Dakota		
Bean	Varietal hybridization and selection to obtain earliness disease resistance and improved regional adaptation Inheritance of earliness	A F Yeager, D H Scott
Muskmelon	Hybridizing of American and foreign forms to obtain earliness size, quality adaptation to the region	Do
Physalis (ground cherry)	Varietal crosses and selection to increase earliness yield and improve yellow color	Do
Squash (*Cucurbita pepo*)	Inheritance of hard rind flesh color rind color Isolation of better adapted strains through inbreeding and selection	Do
Tomato	Inheritance of uniform color determinate growth locule number, earliness fruit size Varietal crosses and selection to obtain high yield quality, and earliness in northern Great Plains area	Do
Watermelon	Inbreeding and selection of heterogeneous foreign introductions to obtain varieties adapted to the region	Do
Ohio		
Beet	Sib mating of inbred selections to obtain superior color and absence of zoning in cannery beets	I C Hoffman, H D Brown
Cabbage	Inbreeding and selection to obtain more uniform and productive strains of Golden Acre	Do
Lettuce	Selection for tipburn resistance in greenhouse strains of Grand Rapids	Do
Tomato	Selection of greenhouse strains of Marhio	Do
	Interspecific crossing and backcrossing to obtain cladosporium resistance	L J Alexander
Oklahoma		
Sweetpotato	Hill unit selection in Nancy Hall and Porto Rico for increased yield, uniformity, and typical shape	E F Burk
Pennsylvania		
Cabbage	Line selection for higher yield, uniformity, and better storage quality	C F Myers, H K Fleming
Tomato	Inheritance of skin and flesh color in the Orange tomato Varietal crossing and selection for improved earliness, fruit shape, uniformity, and yield	Do
Puerto Rico (University station)		
Cucumber	Inbreeding, crossing, and selection for downy mildew resistance and adaptation to tropical conditions	A Roque
Eggplant	Inbreeding, crossing, and selection for resistance to bacterial wilt, for superior quality, and adaptability	Do
Tomato	Hybridization of commercial and native varieties for resistance to bacterial wilt and for improved adaptability and shipping qualities	Do
Puerto Rico (Federal station)		
Sweet corn	Inbreeding, crossing, and backcrossing sweet and native field types for resistance to stripe and to earworms, for good quality and adaptation to the Tropics	R L. Davis.

Table 6.—*Recent vegetable breeding activities of State and Federal agencies in the United States*—Continued

State or department and crop	Nature of studies	Personnel
Rhode Island:		
Eggplant	Pure-line selection, hybridizing varietal inbreds, and selection to develop wilt resistance in good commercial types.	T. E. Odland, F. K. Crandall.
South Carolina:		
Asparagus	Selection to obtain higher yield, uniformity, and adaptation to South Carolina conditions.	J. B. Edmond, L. E. Scott.
Bean	Intervarietal crosses and selection to obtain increased yield, tolerance to mildew and mosaic, earliness, tolerance to adverse growing conditions in South Atlantic areas.	J. M. Jenkins, Jr.
Okra	Pure-line selection for improved uniformity, quality, yield, and spineless pods.	R. A. McGinty, F. S. Andrews.
Sweetpotato	Hill unit selection for improved yield and uniformity	J. B. Edmond.
Tennessee:		
Tomato	Selection for fusarium wilt resistance	(S. H. Essary), C. D. Sherbakoff, B. D. Drain.
Texas:		
Onion	Selection for resistance to pink root and freedom from splits.	L. R. Hawthorn.
Peanut	Pure-line selection for increased yield, earliness, and oil content of Spanish type.	G. T. McNess.
Tomato	Intertype and intervarietal crosses and selection to develop freedom from puffy fruits. Inheritance of tendency to puffiness.	J. F. Wood, L. R. Hawthorn, S. H. Yarnell.
Sweet corn	Production of sweet corn adapted to Texas	P. C. Mangelsdorf.
Utah:		
Celery	Selection for uniform type and resistance to wilt in Utah variety.	A. L. Wilson.
Onion	Inbreeding and mass selection to improve yield, uniformity of shape, and keeping quality in Sweet Spanish.	Do.
Tomato	Selection to improve uniformity and obtain wilt resistance in Greater Baltimore and Stone types adapted to Utah conditions.	Do.
Vermont:		
Squash	Inbreeding Hubbard squash to improve uniformity, quality, and yield.	M. B. Cummings, E. W. Jenkins.
Virginia:		
Bean	Hybridization and selection for rust resistance, high yield and quality. Inheritance of rust resistance.	S. A. Wingard.
Peanut (cooperating with Department).	Pure-line selection to obtain high yielding very large-seeded strains of Virginia type.	E. T. Batten, J. H. Beattie.[1]
Virginia (Truck station):		
Kale	Pure-line selection for deeper green color and resistance to cold.	H. H. Zimmerley.
Spinach	Varietal hybridization and selection for resistance to cold, heat, mosaic ("blight"), and quick bolting; high yield and attractive savoy-leaved type.	(L. B. Smith), H. H. Zimmerley.
Washington:		
Tomato	Hybridization and selection to obtain early, locally adapted sorts.	C. L. Vincent, L. K. Jones.
West Virginia:		
Watermelon	Inheritance of resistance to certain forms of *Fusarium niveum*. Crossing and backcrossing nonedible resistant and edible susceptible forms to obtain edible resistant variety. Cytological studies of above material.	(L. S. Bennett), T. C. McIlvane, J. A. Rigney.
Wisconsin:		
Bean	Hybridization and selection to obtain mosaic-resistant snap beans of high quality and adaptation to Wisconsin.	J. C. Walker, W. H. Pierce.
Broccoli (sprouting)	Mass selection for improved head size and uniformity	O. B. Combs.
Cabbage (cooperating with Department).	Inbreeding and selection for yellows-resistant strains of the several commercial types. Determination of genetic nature and inheritance of different types of resistance.	(L. R. Jones, L. M. Blank), J. C. Walker.
	Inbreeding and selection for club-root resistance in crucifers.	J. C. Walker, R. H. Larson.
Eggplant	Hybridization and selection for increased size and earliness.	O. B. Combs.
Onion (cooperating with Department).	Hybridization and selection for smut resistance in onions.	J. C. Walker, H. A. Jones.

[1] Of U. S. Department of Agriculture.

TABLE 6.—*Recent vegetable breeding activities of State and Federal agencies in the United States*—Continued

State or department and crop	Nature of studies	Personnel
Wisconsin—Contd.		
Pea	Hybridization and selection for obtaining more productive, higher quality wilt resistant peas adapted to Wisconsin conditions	F J Delwiche (E J Renard)
	Inheritance of rogues	(F J Renard)
	Inheritance of resistance to fusarium wilt	(B L Wade)
Radish	Mass selection to improve uniformity and earliness of Scarlet Globe	O B Combs
Tomato	Hybridization and selection to improve fruit size and fruit setting under greenhouse conditions in winter	Do
Department of Agriculture		
Bean (snap and field)	Hybridization and selection among wide range of types to obtain	
	(1) Curly top resistance in garden and additional field types	(W W Tracy Jr)[1] B F Dana
	(2) Resistance to mosaic, rust bacterial blight and root rot in market, canning and field types	B L Wade W J Zaumeyer C F Poole, L L Harter
	(3) 'Multiple' resistance to all known strains of anthracnose	C F Andrus
	Inheritance of mosaic resistance (cooperative with Wisconsin)	(M C Parker)
	Inheritance of resistance to rust, blight and mosaic	B L Wade C F Poole, W J Zaumeyer
Bean (lima)	Inheritance of plant habit and seed coat color and pattern Varietal hybridization and selection to obtain increased setting of pods in the large seeded types increasing thickness and number of seeds per pod in small seeded types increased earliness	Roy Magruder
Beet	Development of highly self fertile inbred strains of good commercial type to improve uniformity and facility of maintaining varietal or strain characteristics	Do
	Inheritance of a variegated red color in the root	Do
	Crossing garden and curly top resistant sugar beet and selection to obtain curly top resistant garden varieties	B F Dana
Cabbage	Inbreeding and hybridization and selection to obtain a round, short core high quality, winter hardy non bolting variety for the South Atlantic and Southeastern States (See also Wisconsin, cabbage)	B L Wade C F Poole
Cucumber	Inbreeding and hybridization and selection among American and Asiatic types to obtain good commercial slicing and pickling varieties resistant to mosaic, bacterial wilt, and downy mildew 'Multiple' resistance is ultimate object	W S Porte S P Doolittle
Lettuce	Hybridization among American and foreign sorts and selection to obtain	
	(1) Resistance to brown blight and powdery mildew and adaptability to numerous different specific southwestern and Pacific coast conditions	I C Jagger T W Whitaker
	(2) Hard heading properties, high quality, resistance to tipburn and adaptability to eastern United States conditions (See also Massachusetts New York, and North Carolina, lettuce)	R C Thompson
	Inheritance of different anthocyanin and green leaf colors, seed color, chlorophyll deficiency, and tipburn resistance	Do
	Inheritance of resistance to brown blight and mildew	T W Whitaker I C Jagger
Muskmelon (in cooperation with California)	Hybridization and selection among American and Asiatic types to obtain varieties resistant to powdery mildew and of high culinary and shipping quality for the Southwest	I C Jagger T W Whitaker (J T Rosa[1] and G W Scott, California)
	Inheritance of resistance to powdery mildew	Do
Pea (part of program in cooperation with California, 1933–36)	Hybridization and selection among available peas of the world that indicate the desired characters, to obtain	B L Wade, W J Zaumeyer (H A Jones California)
	(1) Large podded market types resistant to fusarium wilt, to *Ascochyta*, and to adverse climate	Do
	(2) Resistance to certain mosaics	Do
	(3) Resistance to root rot	Do
	Inheritance of resistance to root rot certain mosaics *Ascochyta*, and certain new fusarium wilts	Do

[1] Deceased

TABLE 6.—*Recent vegetable breeding activities of State and Federal agencies in the United States*—Continued

State or department and crop	Nature of studies	Personnel
Department of Agriculture—Continued.		
Sweet corn	Development of varieties and of inbreds for production of hybrid corns. Objectives: High yield, uniformity, quality, adaptation to the Corn Belt, resistance to bacterial wilt, and specific kernel characteristics adaptable to factory use. Inheritance of quality in sweet × dent crosses. Inheritance of resistance to bacterial wilt, and of albescence.	G. M. Smith (in cooperation with Indiana).
	Hybridization and selection to obtain earworm resistant varieties adapted to the Southeast.	C. F. Poole.
Sweetpotato	Hybridization and selection as well as growing seedlings from open-pollinated seed to obtain variants of higher yield, starch content, earliness, quality, disease resistance or adaptability to specific environments. (Cooperative with La Estacion Experimental Agronomique, Santiago de las Vegas, Cuba; and Federal Experiment Station, Mayaguez, Puerto Rico.)	J. H. Beattie, C. E. Steinbauer, W. K. Bailey (Puerto Rico), (C. de Valle, Cuba).
Tomato (part of program in cooperation with Florida).	Inbreeding and varietal and interspecific hybridization and selection for resistance to wilt, nailhead, and various leaf and virus diseases, and to cracking; for high color, adaptability to shipping, and to specific adverse environments. Inheritance of resistance to wilt.	W. S. Porte, F. L. Wellman, B. L. Wade, C. F. Poole, (W. M. Fifield, Florida).
Watermelon (part in cooperation with California).	Study of seed size and color, flesh and skin color, size of fruit, and growth habit. Resistance to wilt, leaf diseases, weather conditions, and insect damage.	C. F. Poole, (D. R. Porter, California).

TABLE 7.—*Vegetable breeding and improvement work in foreign countries*

NOTE.—The limitations of this very sketchy survey are recognized. Only a part of the world's vegetable breeding activities have been referred to, and important activities have been unavoidably omitted. These few notes, however, testify to the world-wide importance of many general problems and the determination of plant breeders and vegetable growers to obtain ever better crop plants.

Country, institution, and official	Crop	Nature of studies
Australia, Department of Agriculture of New South Wales, Sydney; H. Wenholz, director of plant breeding.	Bean, broad	Adaptation studies of foreign introductions.
	Bean, snap	Hybridization and selection for higher yield, better adaptation and resistance to bacterial blight, anthracnose, mosaic, and dry root rot. Canadian Wonder × Refugee H. 3263 (U. S. D. A.) and Canadian Wonder × Murunga are promising unfixed early disease-resistant hybrids. Tweed Wonder × Keeney Refugee is a promising fixed early blight-resistant hybrid. New variety introduced: Hawkesbury Wonder, from Tweed Wonder × Keeney Refugee. Best yielding varieties are Canadian Wonder (standard), Hawkesbury Wonder, Staley's Brown Beauty, and Staley Surprise. Location: Hawkesbury Agricultural College; Bathurst and Grafton Experiment Farms.
	Beet, garden	Selection in self-fertile and close-fertilized lines for improved quality and yield. Best lines to date are from Rapid Red, Ohio Canner, and Detroit Dark Red (from United States). Location: Hawkesbury Agricultural College.
	Beet, silver, or chard	Selection, isolation, and testing of strains; self-fertility being sought; to improve uniformity and type of commercial varieties. Superior strains isolated from local silver beet and Lucullus. Begun 1930. Location: Yanco Experiment Farm.
	Cabbage, cauliflower, brussels sprouts.	Introduction of foreign varieties, testing, strain selection and purification of adapted commercial types. No controlled pollination used, but natural hybrids utilized when of value. Location: Bathurst Experiment Farm.

Table 7.—*Vegetable breeding and improvement work in foreign countries*—Continued

Country, institution, and official	Crop	Nature of studies
Australia, Department of Agriculture of New South Wales, Sydney; H. Wenholz, director of plant breeding.	Celery	Introduction of foreign varieties, testing against local varieties. Utah, Fordhook, and Pascal (commercial United States) and inbreds of Golden Phenomenal, Golden Self Blanching, and Golden Plume (California Agricultural Experiment Station) were most promising.
	Cucumber	Varietal crossing and selection for improvement of uniformity and adaptability of commercial slicing and of "apple" types; inbreeding for mildew resistance; attempts to cross *Cucumis sativus* (susceptible) with *C. anguria* and *C. metuliferus* (resistant) failed. New variety produced: Richmond Green Apple by crossing commercial × Apple. Location: Hawkesbury Agricultural College.
	Lettuce	Introduction and adaptation studies of foreign varieties, followed by selection and breeding. Best introductions for winter crop, Imperial F and Imperial 615 (U. S. D. A.); for summer, Iceberg (United States), and Imperial F. Local variety Yarrimundi is a pure green selected from an Iceberg stock; some resistance to "slimy heart." Location: Hawkesbury Agricultural College.
	Muskmelon	Introduction and adaptation studies of foreign varieties (United States best source of material; Spanish Gold, a Honey Dew type from France, is promising). Varietal crossing and selection for resistance to powdery mildew, using the California-U. S. D. A. mildew-resistant strains with susceptible sorts of high quality; also seeking downy mildew resistance. Location: Yanco Experiment Farm.
	Onion	Objects: To obtain earlier, better storing, more attractive adapted strains free from bolting and thick necks; also resistance to thrips and disease. Dominant varieties grown: Hunter River Brown and Maitland White. Location: Bathurst Experiment Farm and Hawkesbury Agricultural College.
	Pea	Varietal hybridization and selection for good agronomic characters plus resistance to *Fusarium martii* and *Mycosphaerella pinodes*. Most promising hybrid is Yorkshire Hero × Greenfeast. Location: Hawkesbury Agricultural College; Bathurst and Yanco Experiment Farms.
	Peanut	Testing and selection from large number of introductions, varieties, and strains for large-seeded Valencia or Virginia type with light-pink seed coat. Important Javanese introductions of Spanish type are Toeban and Tannah. Location: Grafton Experiment Farm.
	Rhubarb	Study of introductions and selection of seedlings of introductions and local varieties. South Australian Solid Red, a local variety of excellent color, is most valuable producer of promising seedlings. Location: Hawkesbury Agricultural College and Grafton Experiment Farm.
	Squash and pumpkin	Introduction, selection, and hybridization to obtain well-adapted high-quality varieties of uniform size and shape. Varieties released: Ideal, Satisfaction, and two introductions from the United States, Kitchenette Hubbard (Minnesota Agricultural Experiment Station) and Table Queen. Location: Grafton Experiment Farm.
	Sweet corn	Hybridization and selection to obtain high-yielding, vigorous-growing, high-quality sweet corn adapted to local conditions. New variety produced: Hawkesbury Sugar, from crossing dent and sweet types. Location: Hawkesbury Agricultural College.
	Sweetpotato	Production of seedlings from which desirable selections may be made. Seeds obtained from more tropical countries. Extensive introduction of foreign varieties.

TABLE 7.—*Vegetable breeding and improvement work in foreign countries*—Continued

Country, institution, and official	Crop	Nature of studies
Australia, Department of Agriculture of New South Wales, Sydney; H. Wenholz, director of plant breeding.	Sweetpotato	Best varieties: (Local) White Maltese, Wannop and Ashburn (introduced from the Union of Soviet Socialist Republics) N. 85. Location: Hawkesbury Agricultural College and Grafton Experiment Farm.
	Tomato	Introduction of foreign varieties and testing, varietal and species crosses and selection for following objects: (1) Early varieties for staking. Best introductions: Australian Earliana (a farmer's selection), Break o' Day (U. S. D. A.), and Potentate (from England). (2) Resistance to fusarium wilt, spotted wilt, and leaf mold or *Cladosporium fulvum*. Numerous crosses of Red Currant with commercial varieties. Some promising hybrids obtained, showing resistance to fusarium wilt: Australian Earliana × Break o' Day and Earliana × Red Currant. Latter resistant to spotted wilt. Leafmold-resistant strains by L. J. Alexander of Ohio being used in crosses. (3) Main-crop pulping varieties. Most promising hybrid: Red Pepper × Earliana. Varieties in current use: Norana (from north coast); Newport 4 and Master Marglobe (from United States). (4) Forcing varieties. Best current varieties: Planter's Favorite (a farmer's selection) and Potentate (from England). Location: Hawkesbury Agricultural College; Bathurst, Grafton, and Yanco Experiment Farms.
	Watermelon	Selection for good market type and resistance to fusarium wilt and anthracnose. New variety produced: Wilt Resistant Thurmond Grey, by selection from variety locally called Dark Seeded Grey Monarch. Location: Hawkesbury Agricultural College.
Brazil, Institute Agronomico do Estado de São Paulo, Campinas; C. A. Krug, head of genetics department.	Beans	Pure-line selection to improve stocks of main commercial varieties grown in Brazil. Varietal and species crosses to be made in breeding for regional adaptability and resistance to mosaic, anthracnose, and mildew (new work).
	Tomato	Introduced foreign varieties and local sorts studied for disease resistance and other valuable characters. Hybridization and selection will follow (new work).
Costa Rica, Department of Agriculture, Puntarenas; Alan Kelso, chief of propagation service.		Selection of several wild native or naturalized vegetable plants for adapting them to economic use; tomato and a number of leaf vegetables are included.
Czechoslovakia, State Institute for Horticultural Research, Průhonice; Ing. Fr. Landovsky, chief of division for vegetable and seed production.	Cabbage	Hybridization and selection for increased earliness, yield, quality, and improved local or special adaptations. Hybridization and selection for hardiness to permit overwintering in the open field. Promising selection from hybrid F_3 of Groots × Kärnten.
	Cucumber, onion	Selection for stock improvement in local varieties.
	Tomato	New variety produced: Průhonice, by crossing Lucullus × Tuckswood. Early, resistant to cracking, productive, high quality; for field or forcing.
	Radish	New variety produced: Průhonice, by crossing Triumph × Red Globe. Early (18 to 21 days) high quality, attractive; for field or frame forcing.
Plant Breeding Institute of Fürst Lichtenstein, Lednice; Fr. Frimmel, director.		Studies of hybrid vigor or heterosis are in progress, and hybrid seed or "heterosis seed" of tomato and spinach are produced on a large scale.
	Cucumber	Special interest in cucumber breeding. New variety produced: Zmojemska Nakladacka, a variety for the conserving industry.
	Tomato	Hybridization and selection with special reference to requirements of local growers and canners. New varieties produced: (1) Blondkopfchen, by crossing Yellow Cherry × Prinz Borghese. Grown for canning. More productive than Yellow Cherry. (2) Two other varieties, not named, by crossing Lucullus × Prinz Borghese and Coopers × Ficarazzi, respectively. For canning and market.

TABLE 7.—*Vegetable breeding and improvement work in foreign countries*—Continued

Country, institution, and official	Crop	Nature of studies
Plant Breeding Institute of Fürst Lichtenstein, Lednice, Fr Frimmel, director	Other vegetables	Beans for canning, red peppers, and melons ar receiving attention A number of commercial firms take special pride in their stocks of cucumbers, onions, kohlrabi, and celeriac or turnip-rooted celery
Denmark (Reported by Niels Esbjerg, State Experiment Station, Blangsted)		Research stations in Denmark are chiefly engaged in variety, strain and stock-testing, or seed-control work Vegetable improvement work is being done by commercial agencies, the resulting strains being submitted to Government agencies for recognition before going into trade channels State Experiment Station at Blangsted produced improved celeriac and is selecting cauliflower for cold resistance Selection and progeny testing is principal method used, with minor attention to hybridization Increasing work in disease-resistant selections largely on account of export trade to United States Some Danish firms reporting improvement work A Hansens, Kastrup—Cabbage, cauliflower, spinach, radish, and carrot Chr Olsen, Odense—Cabbage, cauliflower, kale, brussels sprouts, radish, carrot, lettuce, celeriac, spinach J C Helm Petersen & Co , Aarhus—Cabbage, carrot, beet, spinach, turnip-rooted parsley J E Ohlsens Enke, Copenhagen—Cabbage, brussels sprouts, kale, celery, radish, greenhouse lettuce, spinach, tomato, peas, snap beans Hybridization work with tomato, search for "velvet spot" resistance Hybridization with peas and beans Hjalmar Hartmann & Co , Copenhagen—Cabbage and cauliflower Union of Danish Cooperative Societies, Taastrup—Pure line selection of beans and peas Hybridization and progeny testing of cabb ge, beet, and pickling cucumber Progeny testing of onion, turnip-rooted parsley, radish, lettuce, spinach, and tomato
England		
Horticultural Research Station of Cambridge University, Cambridge, D Boyes, director	Broccoli	Production of Roscoff types of good curd texture, disease resistance, and adaptability to specific localities in England having different weather conditions
	Brussels sprouts	Object of work, to obtain varieties with small sprouts for canning or special markets, and varieties adapted to special conditions such as fen soils
	Cauliflower	Early, winter-hardy varieties are sought
	Onion	Production of English types for spring sowing and Spanish types adapted to England
	Parsnip	Production of half-long, smooth, white varieties for commercial use
	Pea	Production of new sorts for canning, hardy types for fall planting, and multipodded types Improved varieties produced have been privately distributed to supporters of the work (subscribers) and are not on the market
The Experimental and Research Station, Cheshunt, W F Bewley, director.		This station deals only with greenhouse crops
	Cucumber	Breeding for a short-necked disease-resistant variety
	Lettuce	Breeding for short-day types for winter culture
	Tomato	Breeding for high yield, quality, and resistance to *Cladosporium fulvum* Productions are distributed first to subscribers who support the research, later to general public Tomato E S 1 and Cheshunt Early Giant lettuce are in general cultivation
The Sealy-Hayne Agricultural College, Newton Abbot, Devon, F. R Horne, professor of botany	Winter cauliflower or broccoli	Intervarietal and intertype hybridization to obtain succession of maturity, sorts both earlier and later than those available Roscoff, Cornish, Angers, and Italian strains being used in breeding, although only first 2 are at present adapted to the environment Some promising hybrid progenies

TABLE 7.—*Vegetable breeding and improvement work in foreign countries*—Continued

Country, institution, and official	Crop	Nature of studies
Scotland, The Scottish Society for Research in Plant Breeding, Carstophine, Edinburgh, William Robb, director		Breeding and improvement work in progress upon swedes or rutabagas
Germany		
Versuchs- und Forschungsanstalt für Wein Obst- und Gartenbau Geisenheim, Professor Dr Rudolff, director	Tomato	Breeding and improvement work in progress
Institut für Pflanzenbau und Pflanzensuchtung der Universität, Halle Professor Dr Roemer, director	*Brassica* spp	Intertype and interspecific crosses studied with reference to fertility relationships and inheritance of specific characters with a view to possible value in future breeding work
	Beans, snap	Breeding for resistance to *Colletotrichum* in beans for canning
	Peas	Breeding work in progress for increased yield and earliness of sweet varieties
Kaiser Wilhelm Institut für Zuchtungsforschung, Muncheberg Professor Dr Rudorf, director	Rhubarb	Breeding work in progress for improved red color of petrioles, lower acid content, more upright growth, earliness, and disease resistance
	Tomato	Work in charge of Dr Sengbusch Intervarietal and interspecies crosses and selection (*Lycopersicon esculentum* and *L pimpinellifolium*) to obtain improved earliness, freedom from fruit cracking and leaf rolling, superior eating and keeping qualities, resistance to cold and *Cladosporium* Promising hybrids have been obtained and are being studied further
Gartnerlehranstatt der Landesbauerushaft Kurmark, Oranienburg-Luisenbof, Dr Bonhert, agricultural adviser	Kohlrabi	Breeding for late frost resistance high quality, small leaves, earliness, is being started
	Tomato	Promising results are being obtained in breeding for increased earliness, resistance to fruit cracking, and *Phytophthora*
Staatliche Versuchs und Forschungsanstalt fur Gartenbau, Pillnitz Professor Schindler, director	Asparagus	Crossing of selected parent plants followed by selection for earlier, stronger growing, rust resistant, tender varieties of good flavor
	Caraway	Selection for improved seed setting, uniformity, earliness, bright seed color, high oil content
	Dill	Selection for higher quality, improved seed setting, uniformity of ripening
	Mustard	Selection for large seed, high oil content, earliness, and uniformity of ripening
Staatliche Lehr und Forschungsanstalt für Gartenbau, Weihenstephan, Professor Bickel, director	Brussels sprouts	Improvement in winter hardiness, earliness, and uniformity of growth and bud formation
	Cabbage	Improvement in growth and head formation, storage qualities, solidity, and head leaf color
	Kohlrabi	Breeding white forcing varieties with more tender flesh, improved form, upright uniform leaves, earliness, resistance to cold
	Lettuce	Breeding for two different types (1) Very quick growing sort for forcing in hotbeds and (2) a larger slower growing sort for coldframes and open ground
	Tomato (forcing)	Breeding for rounder, brighter colored fruit, higher yield, and resistance to *Cladosporium* Resistance of practical value has been obtained, but improvement of fruit characters of such sorts must be continued
Japan, Imperial Horticultural Experiment Station, Okitsu, T Tanikawa, acting director	Asparagus	Testing and selection of promising varieties and strains Data for 1927 to 1936
	Brassica sp	Fundamental research in genetics with special reference to sterilities, compatibilities, effects of inbreeding, and studies of hybrid vigor (1924–32)
	Eggplant	Hybridization and selection for resistance to "blue rot", improved yield, uniformity, and quality Several promising strains obtained (1925 to date)
	Pea	New work started in breeding canning varieties adapted to Japan, by hybridization and selection Also fundamental research in genetics (1935)
	Tomato	New work started for production of new varieties for Japan, for market purposes

Mexico, Instituto Biotecnico. Work at numerous locations. Reported by G. Gandara.	Bean	Obtained a thick-rooted hybrid variety, Campotillo, from Spanish variety of *Phaseolus vulgaris* crossed with Mexican variety of *P. coccineus*.
	Cucurbita sp.	Acclimatization studies of different varieties.
	Tomato	Studies of factors responsible for association of red and yellow color with certain quality characteristics as sweetness or acidity.
	Other vegetables	Acclimatization and disease resistance studies being made on numerous local and introduced varieties of broadbean, chickpea, peanut, muskmelon, and watermelon.
Norway, Government Experiment Station in Vegetable Culture, Kvrthamar, St. Jordal; A. H. Bremer, director. (This station succeeded the former institution known as The Garden Cultivation Friends Experiment Station in 1919.)	Bean, pole	Pure-line selection for early, productive green and wax pole types that can be profitably grown in Norway. Erstling only successful variety at present, yields 30 percent more than any dwarf type tested. Expect to release 1 or more new varieties in 1937.
	Cucumber	Hybridization and selection for very early varieties of acceptable form and quality adapted to Norway. Commonly grown early variety, Muromsk, has low quality and good yield. Is being crossed with high-quality Russiskdrue and Reinische Vargebirge.
	Lettuce	Hybridization of varieties of differing responses to day length to obtain varieties adapted to short, long, and rapidly changing day lengths.
	Muskmelon	Cannot be grown in the open. Hybridization and selection for varieties adapted to forcing under Norwegian conditions.
	Pea	Pure-line selection started by K. Weydahl in 1915 led to introduction of stocks of 6 well-adapted strains in 1922, namely, Engelsk Sabel, Witham Wonder, Ne Plus Ultra Marrow, Saxa, Burton Snabel, and Early June. Hybridization and selection for better adapted types, accompanied by genetic studies; linkage shown between tall plant and parchment in pod with 4 to 5 percent crossing over. Two dwarf large-pod, parchment-free sorts introduced in 1929—Karl Weydahl and Bremers Marrow Sugar. Bremers Early Sugar selected from Sabel × Saxa released in 1931. Numerous hybrids at hand and genetic studies in progress.
(Historical notes on Norwegian vegetable varieties based on information furnished by Prof. Olav. Moen, of the Agricultural High School, Aas.)		Norwegian varietal improvement offers particular difficulties because of the far northern location and the sharp climatic contrasts existing within short distances, as coast and valley versus mountains; and windward versus leeward sides of the mountains.
	Bean	Skard selected an earlier bean than Erstling from Reistad. Grau obtained Olsak by varietal hybridization, also wax beans named Oslo Taro and Smarbukk. Bergsgubber is a Norwegian selection from Nordstjernen.
	Cabbage	Norwegian stocks of Amager are distinct and the results of numerous growers' selections for adaptation to specific conditions. Various strains as Berby, Amot, Fales Blatopp, Sandveds, Toten, and others. Moens Kvitkal result of many years' selection. Rossebo, Jatun, Stavanger Torv, and Jatunsalgets Vinterkal are results of varietal crossing.
	Pea	Chr. Olsen started wrinkled-pea improvement by selection in 1830, and many of present best varieties believed result of his work, as Grimstead Gartneris, Handes, and Bakkes.
	Tomato	Lund has developed an outdoor strain of Danish Export and of Hannestad, and a forcing strain of Kondine for Norway conditions.

Sweden:		
Agricultural Experiment Station, Alnarp; Carl G. Dahl.	Bean	Hybridization and selection for improved yield earliness, quality, and adaptabity to Sweden; strains 3 to 5 days earlier than any known sort obtained. also high-yielding wax sorts. All require further selection before introduction.
	Brussels sprouts	Hybridization and selection for high yield and cold resistance; work in progress.
	Cabbage	Common × savoy cabbage crosses made for milder flavor, good storage quality, and high yield. Alnarp cabbage No. 1 and Alnarp cabbage No. 2 released to the trade.
	Pea	Hybridization and selection for high-quality, high-yielding, large-podded, sweet, wilt-resistant peas for home, market, and canning. Many promising lines obtained. Alnarp Sten's No. 1 and Alnarp Sten's No. 2, released to the trade in 1927. They are high yielding and wilt resistant. Alnarp Sabel is a selection from Sabel. Numerous strains will soon be ready for release.
Horticultural Institute of W. Weibull & Co., Weibullsholms, Landskrona; H. Lamprecht, head of technical staff.		Selection and hybridization to obtain high-quality, early, productive varieties adapted to Swedish conditions of culture and use.
	Bean, snap	Stella, selected from strain grown on an old farm in Sweden, introduced to the trade about 1925. Early, thin hull, high yield. Alabaster II obtained through pedigree selection from Swedish variety Upplands; resistant to pod spot. Express, a wax variety introduced in 1932, was obtained by crossing German variety Daddel with an unknown. Very early and high yielding.
	Carrot	Regulas, a superior storage carrot, of qualities otherwise similar to Chantenay.
	Cauliflower	Giant Swedish No. 147. Obtained from cross of Giant Danish and an unnamed variety. Somewhat drought-resistant.
	Cucumber	Perseus, developed from Rockford. Earlier and more productive.
	Pea	Nanna, a sugar type, obtained from cross of Furst Bismarck × a red-flowering sort similar to Gray Giant. High yield, quality, and good adaptability. Extra Rapid, selected from Rapid, which is uneven in earliness. Said to be earliest pea grown. Released in 1927. Sylva, a marrow pea, was selected from Fairbeards Nonpareil, beginning in 1918. Released in 1925. Luna, an edible podded sort, from cross of Roi des Gourmands and Witham Wonder.
	Spinach	Valkyria II was selected from Valkyria and introduced in 1925. The plants are monoecious, high-yielding, resistant to *Peronospora*. Color somewhat light. Herta is dark green, dominantly but not completely monoecious, quick growing. Derived from cross of Valkyria and Victoria.
L. Daehnfeldts and G. Hylten-Cavallius, seedsmen, Halsingborg; Ernst Nilsson, in charge.		Varietal crossing and selection to develop high-yielding, high-quality strains and varieties adapted to conditions in Sweden. Varieties introduced to the trade as indicated.
	Bean, field	Risbrinken, selected from unnamed variety. Early and resistant to pod spot. Dwarf Brown, introduced in 1933, from cross between Nordstern and a brown variety in 1919. Said to be very hardy and adapted to northern Sweden.
	Bean, wax	A pedigree selection of Beurré Nain Sans Rivale adapted to Swedish conditions.
	Pea	Sugar types as follows: Norrlands, from Pilot × Bismarck; Early Giant, from Sabel × Laxton; Elitsabel, from Sabel × King; Giant Sabel, selected from English Sabel; Giant Sabel Elit, from Stens × English Sabel; Kings, a selected strain of Roi des Gourmands; Improved King, from Giant Sabel × King. Numerous strains of marrow and sugar peas are in process of development, principally by varietal crossing and selection.

Union of Soviet Socialist Republics.		Unfortunately, up-to-date information from plant breeders in the Union of Soviet Socialist Republics could not be obtained in time for including in this report, but it should be pointed out that they are among the most active workers in the field today. Special emphasis has been placed on thorough exploration of all promising parts of the world for obtaining varieties and breeding material of value. Very extensive programs are in progress at numerous locations for studying introduced materials in detail and for large-scale hybridization and selection work. Large resources and great energy are being devoted to this work. There is no doubt that results of considerable practical and scientific importance are being obtained.

IMPROVEMENT OF SWEET CORN

C. F. POOLE, Cytologist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

THE only genetic difference between the composition of a sweet corn kernel and that of field corn is due to a single recessive gene out of the hundreds or thousands of genes in corn. This gene makes the sugary condition of the kernel persist in sweet corn; or, in other words, prevents the conversion of some of the sugar into starch.

The first recorded observation of sweet corn by white men appeared in 1779, when Lt. Richard Bagnall, of Sullivan's Indian Expedition, returned from an Indian campaign to the west of the Susquehanna with several sugary kerneled ears procured from the natives. We know today that the Iroquois Indians cultivated at least two sweet varieties, one white and one black—similar to Black Mexican—and that the Indians of the upper Missouri included four sweet corns among the 104 corn varieties they cultivated (*45*).[1]

In 1828 Thorburn's seed catalog listed a single sweet corn variety, and by 1881 the number of advertised varieties in all seed catalogs had increased to 16. Today, by reason of an increased interest in the production of hybrid sweet corn, it would be difficult to estimate with any accuracy the number of sweet corn varieties and stocks on sale, but it must run into many hundreds.

Considering its popularity, it may be surprising to some that the region of sweet corn cultivation is confined practically to southern Canada and the northern half of the United States. There are three reasons for this restricted distribution. (1) The period during which sweet corn kernels remain sweet after picking is of very short duration, and at the higher temperatures farther south the sugars are rapidly converted to starch. (2) The corn earworm, *Heliothis obsoleta* Fabr., is less injurious or is absent only in latitudes with winter temperatures low enough to prevent winter pupation of the larvae. Earworm injury in the Southern States is so great that the main dependence for roasting ears is the naturally more resistant field corn, including such varieties as Trucker's Favorite, Mexican June, and Tuxpan. These varieties, together with practically all the field corns of the South, have become relatively resistant to the corn earworm through natural selection extending over a long period. This fact is being used to good advantage (*38*) in converting some of the leading southern dents into highly resistant sweet corns by appropriate crosses. The third reason is much like the second, but in this case the condition is bacterial wilt instead of an insect. This disease is especially severe in the South,

[1] Italic numbers in parentheses refer to Literature Cited, p. 392.

and sweet corn varieties are much more susceptible in general than the southern field corns.

Prior to 1900, when the rediscovery by three European botanists of Mendel's paper on hybridization in garden peas aroused greater plant breeding activity than had hitherto been known, the literature of sweet corn breeding was confined to descriptions of variety tests. An examination of the experiment station bulletins around 1889, especially in Illinois, Indiana, and Nebraska, shows the names of some 75 sweet corn varieties classified according to earliness or lateness of maturity, color of kernels, and suitability for cultivation in those States. Some attempts were then made to standardize names and show which were synonymous. Early station bulletins from North Carolina and Louisiana mentioned that field corns were productive under local conditions, but sweet corn could not be successfully cultivated because of the damage inflicted by the corn earworm.

With few exceptions the men then practicing plant breeding failed to conceive of the possibility of hybridizing different stocks of corn with a view to producing new types for special purposes. Mendel's paper, however, by clearly stating certain definite laws of inheritance operating when character contrasts are introduced in a cross, showed that breeding for special purposes could be done systematically and with comparative ease. After 1900 the character of experiment station publications changed from lists of varieties to reports of crosses made with definite objectives, such as production of extra early maturing stocks, and of better canning varieties with deeper and more tender kernels, increasing the uniformity of all characteristics in canning varieties, and increasing yield and resistance to disease or insect attack.

WE CAN *hardly overstress the importance to the canned-corn industry of the all-embracing uniformity of characters resulting from the production of crosses and top crosses of inbred lines of sweet corn. The uniformity in texture and consistency of grains and in shape and size of ears has practically revolutionized the machinery and methods of handling in the cannery; and furthermore, in the field the even placing of the ears on the stalks and the uniformity with which an entire field reaches maturity have brought economies never before possible. These advantages are also evident in more recent cannery practices, such as putting up corn in frozen packs, and an increase in the whole-grain method of removing kernels from the cobs. It is estimated that about 80 percent of the yellow sweet corn grown for canning in 1937 will be from hybrid seed, and half of this, or 40 percent of all yellow cannery sweet corn, will be Golden Cross Bantam.*

Among the first sweet corn breeders to work for specific ends without knowledge of Mendel's laws was a Maryland physician, Stabler (*44*). In 1879 he planted alternate rows of Burr Mammoth and Stowell Evergreen and removed the tassels from the latter, thereby obtaining hybrid seed from which he selected an improved canning variety called Roslyn Hybrid Sweet. The new variety had large ears, straight rows, deep kernels, small cobs, and a higher yield than either parent. Stabler later produced an earlier maturing evergreen variety, called Early Stabler, by selecting seed from the first ears to set. He recognized that even though the ears were open pollinated, so that the pollen parent was unknown, it had to be early maturing to pollinate an early silking plant, and consequently the ensuing selections would be earlier than the original stock.

The interest aroused in genetics and plant breeding after 1900 was promptly applied to sweet corn, first by Halsted, Kelsey, and their colleagues in New Jersey, and later by East in Connecticut, Pearl, Surface, and Sax in Maine, and Huelsen and Gillis in Illinois. These workers established inbred lines through artificial self-pollination to produce true breeding stocks and to eliminate defective characters. With improved inbred lines they expected to analyze the factors of inheritance and produce newly constructed varieties from specifications found in both parent stocks. At about the time of the Maine work, Collins and Kempton (*7*), of the United States Department of Agriculture, made the first deliberate attempt to breed a sweet corn resistant to the corn earworm by crossing resistant dent varieties with susceptible sweet corn varieties.

SWEET CORN BREEDING

Sweet corn is chiefly used as a canning vegetable almost throughout the world and as a green garden vegetable in regions favoring its cultivation. The activities of sweet corn breeders are predetermined by these uses somewhat along the following lines:

1. For the canning industry, the production of high-yielding uniform hybrid stocks with good quality, by crossing inbred lines among themselves or top crossing inbred lines as pollen parents on commercial varieties as seed parents. Both practices insure greater uniformity in time of maturity, as well as in other characters, and increased yield.

2. Extension of the geographic range of the crop farther southward through the development of improved earworm-resistant varieties of sweet types by hybridization of susceptible varieties of good quality with naturally resistant field corns; and the extension of the range northward by selecting extra early maturing stocks.

Shortly before the timely rediscovery of Mendel's paper, Halsted and his coworkers (*13, 14, 15, 16, 17, 18, 19, 20, 21*) of New Jersey in 1898 began breeding sweet corn with the object of combining in one variety the best features of Black Mexican and Egyptian (Washington Market), which had white kernels. They observed that crossed seed in this case could easily be identified on ears of Egyptian plants, since corn has the advantage of exhibiting xenia.[2] For example, black aleurone color is dominant to clear in this cross, and any kernels on a plant with white ears that chance to be pollinated by pollen grains

[2] See the article on Fundamentals of Heredity for Breeders, in this Yearbook.

from a black parent will develop into black instead of white kernels. Black Mexican and white Egyptian occupied adjoining rows and the breeders commenced their work merely by choosing black seeds from Egyptian ears. Faster progress was made by raising a winter generation in the greenhouse, and in their earlier work Halsted and Kelsey selected breeding stock from open pollinated ears. It was not until 1900 that they practiced artificial pollination and not until 1905 that their reports began to include Mendelian terms. Notwithstanding their primitive methods at the beginning, the new variety Voorhees Red Sweet was fairly well fixed when it was released to the public in 1903. The variety combined features from the two parents and in addition exhibited red kernels, a character not expressed in either parent.

Immediately upon adoption of controlled pollination and Mendelian conceptions, Halsted began an extensive hybridization program with sweet corns with the specific object of improving stocks for earliness, higher percentages of two- and three-eared stalks, and recombination of the best features of diverse parents. At first Black Mexican was used as pollen parent with Malakov, an extra-early variety recently introduced from Russia, and with Garwood, Country Gentleman, Striped Evergreen, Banana, and Golden Bantam. Many other varieties were included later, and Black Mexican was omitted when pollination from bagged tassels made xenia no longer important as a device in this work to identify a cross. The problem of adequately testing the new stocks was overcome by enlisting the aid of cooperating farmers. In 1906, seed of six new varieties was widely distributed for trial and the year following four more were added to the number, two of which were given names abbreviated from the two parents, Malamo (Malakov × Premo) and Malakosby (Malakov × Crosby).

At this time Halsted began crossing sweet corns with Iowa Silvermine (white) and Pride of Nishna (yellow), dent corns, further to increase the yield of seed and stover. From the former he derived Silver Sweet by crossing with Stowell Evergreen and Jersey Sweet by crossing with Country Gentleman.

The order of importance of the elements that contribute to quality in sweet corn depends on whether we are considering market varieties or canning varieties. The market gardener places sweetness first, followed by tenderness of the pericarp, or outer covering of the kernel, then consistency or texture of the kernel contents. But since the canner may add extra sugar to the brine, his specifications for the breeder (*9*) place tenderness of the pericarp first and sweetness last, with consistency of kernel as the requirement second in importance.

Sweet Corn for the Cannery

The chief factors in the selection of varieties for use in the canning industry are deep kernels, yellow or white, according to local preferences; uniformity in all characteristics of the plant and ear; satisfactory yields; high quality; and, in regions afflicted with insects or disease, resistance to or escapement from injury. Previous to 1924, the date when practical interest was first aroused in the production of hybrid stocks from crossing inbred sweet corn lines, canned sweet corn was

obtained almost entirely from the four major varieties described in table 1.

TABLE 1.—*Sweet corns used for canning*

Variety	Year introduced	Color	Maturity date	Height	Cut corn at 20 days
				Feet	*Percent*
Crosby	1860	White	Early	5-6	37.2
Stowell Evergreen	1860	do	Intermediate	7-8	45.9
Country Gentleman	1882	do	Late	7	46.1
Golden Bantam	1900	Yellow	Early	5-6	27.4

The data shown as percentage of cut corn at 20 days after the appearance of the silks, as given by Culpepper and Magoon (*8*), are included in order to indicate the efficiency of a variety in producing the deep kernels best suited for canning. This figure is computed by dividing the weight of cut kernels by the total weight before cutting.

A serious drawback of all commercial varieties for canning purposes, however, is the great variability in characters, and especially in the time when individual plants reach maturity. This means that at any given time a large percentage of underripe and overripe ears must be taken, along with those in prime condition. A breeding practice that would increase the uniformity in reaching maturity, shape of ears, or texture of grains, as well as giving increased yield or greater depth of kernels, would be desirable. The increase in uniformity alone would be a great boon to the canning industry because this results in a relatively much larger pack from a given yield in the field. It was shown by G. H. Shull in 1908 that increased yield and a high degree of uniformity in all characteristics would result from crosses between inbred lines. Many years before this, about 1880, W. J. Beal, of the Michigan Agricultural College, observed that hybrid vigor and somewhat greater uniformity resulted from the crossing of commercial varieties in the field. At that time he proposed planting alternate rows of two field varieties, detasseling one and using ears from the detasselled variety to obtain hybrid seed.

MORE RECENT BREEDERS

In the summer of 1907 Pearl and Surface (*39*) in Maine commenced investigations on sweet corn for the specific purpose of producing seed adapted to Maine rather than to Connecticut and Massachusetts—the chief sources of seed. For the production of improved canning varieties their immediate objectives were greater earliness, higher yield, and improved ear shape. They produced inbred lines by inbreeding for several generations and discarded the poorer lines while retaining the better ones. Their contribution to sweet corn breeding practice was the selection of breeding stock on the basis of the performance of the progeny and not upon the appearance of the ear and plant, which had been the practice until that time. In their own words, "the objects of selection must be to discover and separate the desirable genotypes from the poor ones." After 3 years of such work Maine farmers had better locally grown seed than could be purchased elsewhere.

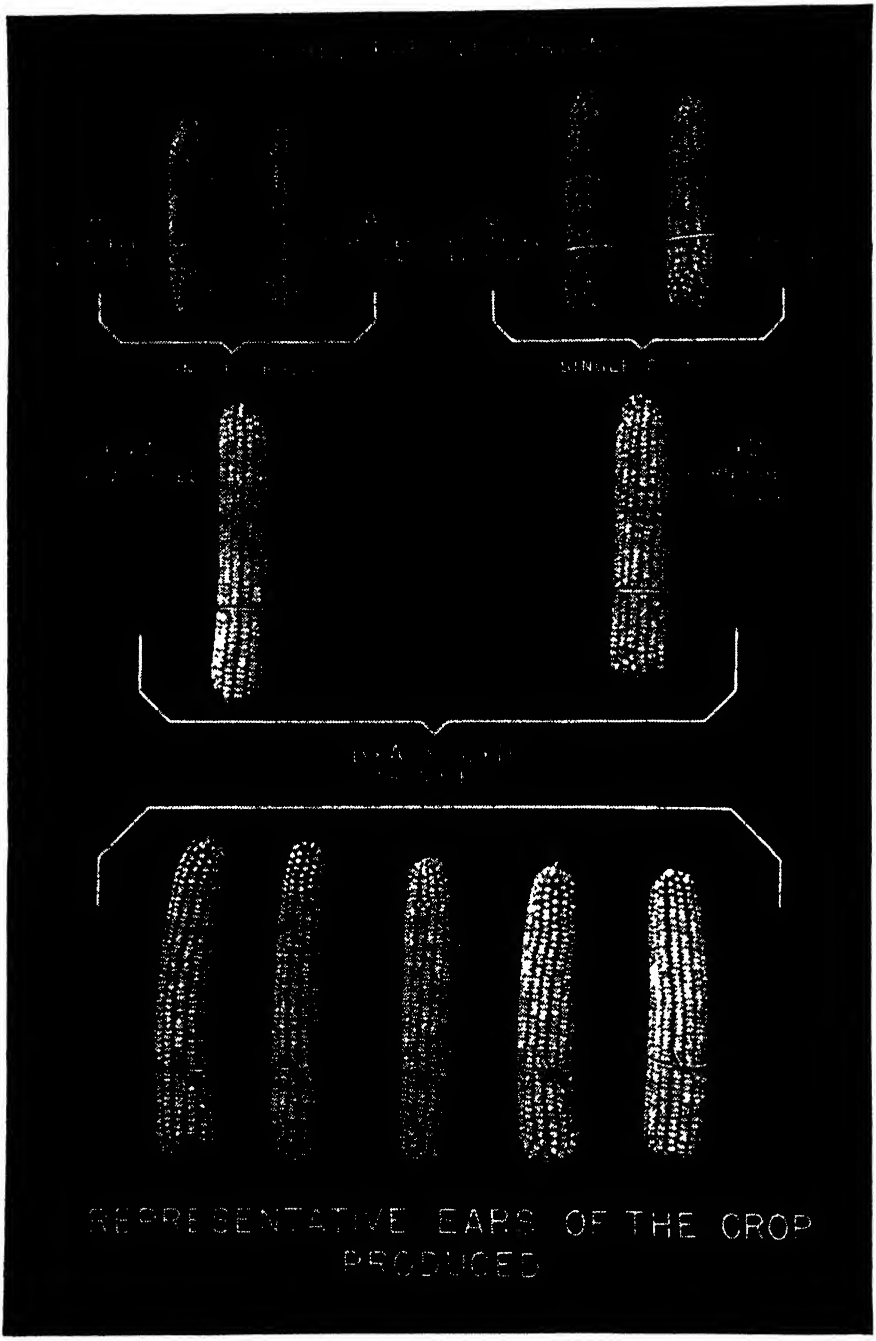

Figure 1.—**Method of producing double-cross hybrid seed corn and representative ears of the crop produced from hybrid seed.**

In Illinois, which, according to the latest statistics, is usually slightly ahead of Iowa as the leading sweet corn State, both in acreage and in total pack, breeding operations were begun about 1926 by Huelsen and Gillis, as reported by Keilholz (*32*). Their methods were much the same as those already in use elsewhere, but they emphasized the improvement of quality by use of the puncture test to identify the most tender lines for use in breeding. The test shows the pressure in grams per square centimeter required to penetrate the pericarp of the corn kernel. Huelsen and Gillis learned that high degrees of tenderness are exhibited in dent corns as well as in sweet corns.

In Connecticut the production on a commercial scale of cross-bred seed from inbred lines in field corn was first practiced in 1921 by George S. Carter, of Clinton (*30*). Shortly thereafter, in 1924, the Connecticut Agricultural Experiment Station introduced an F_1 or first-generation hybrid sweet corn called Redgreen, produced from two inbred lines, one being Stowell Evergreen and the other from a variety of unknown parentage. This hybrid stock was soon grown and canned by the W. N. Clark Canning Co., of Rochester, N. Y., and its superior characters in adaptation to locality, productivity, uniformity of maturing, and quality were immediately recognized.

Redgreen was not as successful elsewhere as in New England, central New York, and certain sections of the Northwest. Today practically every experiment station has several or many such cross-bred stocks, many of which are sold by the leading vegetable seedsmen. The lead in such activities was taken by the Connecticut station (*30, 31*), the Minnesota station (*28*), and the Purdue University station in cooperation with the United States Department of Agriculture. Figures 1 and 2 illustrate the methods and results obtained in producing single- and double-crossed corn.

The most popular and most widely adapted of these hybrid stocks is Golden Cross Bantam, produced about 1927 by Smith (*43*), of the Department, in cooperation with the Purdue University station by crossing Purdue 39 (Purdue Bantam) and Purdue 51, both inbred lines of Golden Bantam. Purdue 39 has attained some degree of commercial importance in its own right by reason of its resistance to bacterial wilt or Stewart's disease (*Aplanobacter stewarti* (E. F. Smith) McC.), high quality, and yield.

The great popularity of Golden Cross Bantam is chiefly due to its yield, canning qualities, uniformity, and resistance to bacterial wilt (figs. 3 and 4). This disease is most serious in latitudes close to 40° north and is of importance mainly in sweet corns, sometimes destroying almost the entire crop. The earlier maturing varieties are most susceptible. A recent study of Stewart's disease (*26*) recognizes two distinct genetic types of resistance: (a) Vigor-correlated, inferred from the fact that vigorous hybrids between some low-resistant inbred strains are more resistant than either parent; and (b) true resistance, shown by the fact that hybrids from low-resistant inbreds are less resistant than hybrids from high-resistant inbreds. Golden Cross Bantam may owe its high degree of resistance to both these causes, since it has hybrid vigor and one of its parents, Purdue 39, is also highly resistant.

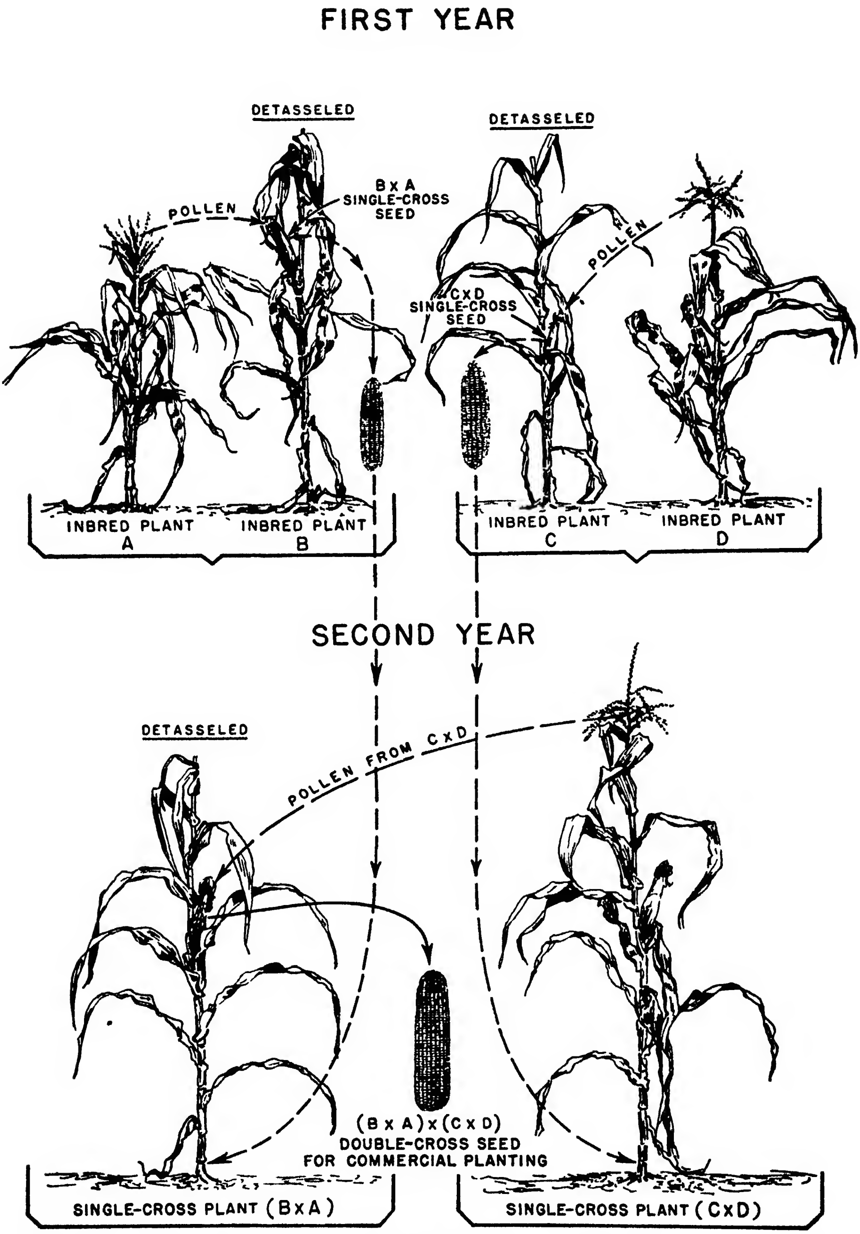

Figure 2.—Diagram of method of crossing inbred plants and the resulting single crosses to produce double-cross hybrid seed.

The tremendous importance of these hybrid sweet corns, and particularly Golden Cross Bantam, is indicated by the fact that it is estimated that about 80 percent of the yellow sweet corn which will

be grown for canning in 1937 will be grown from hybrid seed. It is estimated that half of this, or 40 percent of all yellow cannery sweet corn, will be Golden Cross Bantam

Figure 3.—Golden Cross Bantam, a variety resistant to bacterial wilt or Stewart's disease. It remains healthy on wilt-infected soil and makes a normal crop.

Top-Crossed Sweet Corn

The use of inbred lines as pollen parents crossed on commercial varieties as seed parents—called the top cross—for producing uniformly maturing and high yielding corn stocks was begun at the Connecticut Agricultural Experiment Station in 1917 with field corn The practice was soon used on sweet corn with excellent results, and

in 1935 the station recommended to the trade two early stocks, Spancross C–2 and Marcross C–6, and two midseason stocks, Whipcross C–6.2 and Whipcross C–7.2. In addition to these they recommended for the 1936 trade the following new top crosses: Marcross C–13.2, Burcross C–2, Sencross C–7, Dalecross C–2, Orcross C–2, Coincross C–2, and Stancross C–2. The 1935 seed catalog of one of the vegetable seedsmen listed four top crosses, all of which were produced by its own breeding staff. In recommending the top-cross method, Jones and Singleton (*31*) say:

Figure 4.—Golden Bantam, a variety susceptible to bacterial wilt, growing in infected soil near the plant shown in figure 3. Golden Bantam was practically a total loss in this test.

> From the standpoint of ease of producing seed and the adaptability of this seed, as compared to that of single crosses (between two inbred lines), there is much to be said in favor of variety-inbred crosses (top crosses)

The importance to the canned-corn industry of the all-embracing uniformity of character resulting from the production of crosses and top crosses of inbred lines can hardly be overstressed. The uniformity in texture and consistency of grains and in shape and size of ears has practically revolutionized the machinery and methods of handling in the cannery; and furthermore, in the field the even placing of the ears on the stalks and the uniformity with which an entire field reaches maturity have brought economies never before possible. These advantages are also evident in more recent cannery practices, like putting up corn in frozen packs and the whole-grain method of removing kernels from the cobs. In each instance the uniform texture of grain in single-cross and top-cross stocks of sweet corn makes them superior to the open-pollinated corn varieties.

Market Sweet Corn Breeding

Many of the varieties bred for the canning industry also are suited to market growing. In addition, there is need for extremely early strains for the extreme northern areas of the territory. In the South the question of earworm resistance is of major importance, and, if resistant strains are developed, sweet corn culture may increase in importance in this region.

About 1913 Collins and Kempton (*7*), of the Department, began a study on earworm resistance in dent and sweet corn. They obtained two highly resistant dent varieties, which were crossed with three susceptible sweet varieties, Stowell Evergreen, Early Evergreen, and Cory. The hybrid progenies proved more resistant than the commercial varieties. Prolongation of the husks beyond the tip of the ear and thickness of the husks were found to be associated to some extent with low damage. The evidence indicated that increased resistance of the hybrids also was due to other characters not measured but probably correlated with husk prolongation. The presence of some volatile substances distasteful alike to the moth and larva, but too elusive for measurement, was suggested.

Mangelsdorf, of Texas, crossed the highly earworm-resistant dent varieties, Mexican June and Surcropper, with the sweet variety Country Gentleman, and continued backcrossing to the dent parent for several generations. Eventually he obtained two varieties of sweet corn, Honey June and Surcropper Sugar, which to outward appearances were practically identical in plant characters with their dent parents and were highly resistant to the earworm, but which in addition were sweet. In numerous tests of the adaptation of these two sweet corns to conditions in Texas (*23*, *24*) and in California (*40*, *41*, *42*), the degree of earworm resistance has been demonstrated to be superior to that shown in any other sweet corn varieties with the possible exception of Papago, a commercially unpromising sweet corn produced by Freeman (*12*) at the Arizona station, and of Aunt Mary's Sweet.

Papago was produced from a few sweet grains found in the summer of 1910 on ears of squaw (flour) corn grown by the Papago Indians. Aunt Mary's Sweet is a recently introduced sweet corn from Ohio, which has been carefully nursed from year to year for perhaps a century on a single farm near Darby Plains. Such antiquity suggests Indian origin, and this is the expressed belief of the introducer, L. R. Bonnewitz, of Van Wert, Ohio. The point of Indian origin might well be stressed for Papago and Aunt Mary's Sweet, since it is to be expected that the inherent earworm resistance of maize varieties in possession of the Indians was due to a fixation by natural selection of resistance to earworm attack.

Florida 191 and Suwanee Sugar, recently produced by the Florida station, have given much promise as earworm resistant converted dent-sweet corns when tried in the diverse environments of the Southeast and the far West. More recently, Georgia 439 and Georgia 428 from the Georgia Experiment Station have indicated promise equal to that of the best strains of Honey June (*23*).

In the last 4 or 5 years a number of investigators in widely distant States have independently conducted tests of rather extensive lists of

varieties of sweet corn to determine their earworm resistance and value for market or breeding purposes. In tests at Davis, Calif. (*40*, *41*), Winter Haven, Tex. (*23*, *24*), and Charleston, S. C., certain varieties were consistently outstanding in earworm resistance, namely, Honey June, Surcropper Sugar, Papago, Aunt Mary's Sweet, Florida 191, and Oregon Evergreen. The relative resistance of these sorts varied among the several tests, but they were of the same general degree of resistance.

Even with the high degrees of resistance thus far uncovered, progress in breeding earworm resistant sweet corns is still far from satisfactory. Other hybrids have recently been made by Mangelsdorf in Texas (see the table of introductions in the appendix) and by Poole in California, using southern dent corns like Tuxpan and Davis Prolific that are even more resistant than the first dent parents used in producing Honey June and Surcropper.

Evidence obtained during 2 years of study by the California station has demonstrated, in statistically significant tests, that high earworm resistance is altogether independent of length or thickness of husks.

Other possible factors not correlated with resistance are length of ear, weight of ear, height of plant, and length of time required for maturity (*42*). Promising lines of investigation as yet untried include the search for factors determining volatile compounds that repel laying moths, suggested by Collins and Kempton, measurement of the tightness of the husk covering, and determination of the quality of husk covering. These lines of investigation will require collaboration with specialists outside the field of genetics, or the development of a special technique, before quantitative measurements can be taken.

Although it is still too early to estimate the extent to which these new sweet corns will extend the geographic range of sweet corn cultivation, there is no question regarding the interest of truck and home gardeners in present efforts. Honey June in particular has aroused enthusiasm among Texas and California growers, and one railroad company in Texas has planted large acreages for shipment of green sweet corn to northern points.

GENETICS [3]

THE genetics of sweet corn is the same as the genetics of corn in general, except for the particular genes responsible for the sugary condition of the endosperm. Corn genetics has been so adequately treated in the 1936 Yearbook of Agriculture (*27*) that no further reference is necessary except for considerations peculiar to sweet corn.

As has been said, the only genetic distinction to be drawn between starchy endosperm and sweet endosperm is the fact that the normal gene Su_1 (starchy) at locus 71 on chromosome IV (*10*) in field corn has mutated to su_1 (sugary) in sweet corn. There is another allelomorph of this gene at the same locus, and in addition two nonallelomorphic sugary genes on two other chromosomes than number IV, which will be discussed below. The sugary mutations result not only in a higher total sugar content but also in a persistence of the sugary condition of the endosperm to maturity. All other characteristics of the sweet

[3] This section is written primarily for students or others professionally interested in genetics or breeding.

corn varieties, such as short stature, early maturity, loose husks, etc., are shared in common with field corn.

The investigator who seeks to effect certain combinations between sugary or sweet corns and nonsugary corns may encounter aberrant monohybrid ratios involving the sugary character. These aberrant ratios are due in some cases to the action of genes linked with su_1, but also may be due to other causes (*2, 3, 4, 5, 6, 33, 34, 35*).

Mangelsdorf (*37*) investigated the respective rates of growth of pollen tubes carrying Su_1 and su_1 and finds that Su_1 pollen tubes have an accelerated growth rate at the start and that su_1 pollen tubes grow as fast as Su_1 when the initial handicap is overcome.

In most other cases reported in the literature it appears that when both *Su* and *su* appear together in one organism, the F_2 segregates in entirely normal monohybrid ratios. The first exception was noted in 1920 by Harper (*22*), who reported that when two sugary races were crossed the resultant F_1 was starchy, indicating two nonallelomorphic sugaries. Subsequent investigations have shown that there are indeed two previously unknown nonallelomorphic sugary genes, su_2 on chromosome VI (*11*) and su_3 on chromosome IX (Eyster, unpublished, *10*). Furthermore, there is some evidence that at the su_1 locus on chromosome IV there is a third member of the series, su_1^{am}, producing a sugary kernel not as sweet as su_1, and which apparently is associated with the presence of the gene *du*, dull endosperm, on chromosome X (unpublished communication from Mangelsdorf, also mentioned in *10*).

A condition called "pseudostarchy" has been analyzed by Jones (*29*) and is thought to be caused by the complex interaction of three dominant genes with the su_1 gene. One gene is necessary for the full expression of pseudostarchy, a second inhibits the shrinkage of sugary kernels, whereas the third dominant gene produces an opaque appearance of the dried kernels.

In an investigation of the chemical composition of known endosperm genotypes from crosses of dent × sugary, Lindstrom and Gerhardt (*36*) showed (table 2) an increase of sugars and a decrease of starches for each additional *su* gene (expressed as *s* in table 2) obtained in the recombinations resulting from reciprocal F_1 matings and backcrosses, or in an F_2 generation.

TABLE 2.—*Carbohydrate percentages for whole kernels (moisture-free basis) for different types of crosses and known genotypes*

Cross type [1]	Endosperm genotype	Samples	Total sugar	Dextrin	Starch	Carbohydrate index [2]
		Number	*Percent*	*Percent*	*Percent*	
White dent	*SSS*	3	2.3	1.9	56.6	0.07
Evergreen	*sss*	3	4.9	24.5	27.9	1.05
F_1 (HF × E)	*SSs*	4	2.7	2.1	53.6	.09
F_1 (E × HF)	*ssS*	1	3.6	1.7	56.1	.09
F_1 × E	*SSs*	4	1.8	1.6	57.5	.06
	sss	3	5.3	25.7	23.1	1.34
E × F_1	*ssS*	3	2.2	2.2	55.8	.08
	sss	2	4.5	25.9	27.1	1.12
F_2	*SSS*	4	2.3	2.7	57.5	.09
	sss	3	5.3	29.1	21.6	1.59

[1] HF = High fat strain; E = evergreen parent.

[2] Ratio of total sugar plus dextrin to starch.

In another analysis of chemical composition of known endosperm genotypes involving the sugary gene, Abegg (*1*) demonstrated a cumulative relationship for percentage of crude fat relative to the genes sugary and waxy in the following series:

Genotypes:	Percent of crude fat	Genotypes—Continued.	Percent of crude fat
Su su su Wx wx wx	1.0	*su su su Wx wx wx*	2.6
Su su su wx wx wx	1.4	*su su su wx wx wx*	3.0

The typical ear of corn possesses rows of kernels in even numbers because the female florets of the ear are arranged in pairs, each member of which has two ovules. The rows are straight because only one ovule on each floret develops, and the relatively uncrowded ear displays its kernels in an evenly rowed condition. The sweet corn variety Country Gentleman, however, is unique in the fact that the second ovule of each floret also develops and produces a crowded zigzag or "shoe-peg" condition. Huelsen and Gillis (*25*) investigated the inheritance of the apparently unrowed condition in Country Gentleman by carrying to the F_3 generation a cross between Country Gentleman and Narrow Grain Evergreen, the latter with typical straight rows. Intermediate degrees of zigzagging were sometimes difficult to classify, but on the whole the data conformed quite well to the working hypothesis that the unrowed condition of Country Gentleman was due to the operation of two pairs of recessive genes, $p_1\ p_1$ and $p_2\ p_2$, the chromosomal locations of which have not yet been identified. According to hypothesis the history of this cross is symbolically represented as Narrow Grain Evergreen, rowed $(P_1P_1P_2P_2)\times$ Country Gentleman, unrowed $(p_1p_1p_2p_2.)$

POPCORN BREEDING

ARTHUR M. BRUNSON, Agronomist, Division of Cereal Crops and Diseases, Bureau of Plant Industry

POPCORN is a peculiarly American crop. Not only was it unknown to white men before the discovery of North America, as was all maize, but its cultivation and use for popping is almost entirely restricted to the New World. European visitors frequently express surprise at this unique form in which corn is available for human consumption.

It seems practically certain that popcorn was grown and popped by the Indians before the coming of Columbus. The records, although fragmentary, indicate that popped corn either whole or pulverized was used in native food dishes by various tribes in both North America and South America. Popcorn kernels and specially shaped earthenware dishes thought to be corn poppers have been discovered among prehistoric Indian remains in South America. In early Spanish writings, reference is made to the rituals of the Aztecs in which

> one hour before dawn there sallied forth all these maidens . . . crowned with garlands of maize, toasted and popped, the grains of which resembled orange blossoms, and on their necks thick festoons of the same which passed under the left arm.

BASIS OF POPPING BEHAVIOR

THE phenomenon of popping in corn is not limited to popcorn, but is exhibited to the greatest degree in this subspecies (*Zea mays* var. *everta* Bailey). Many flint corns under proper conditions will pop passably well, and some of the horny dents will occasionally pop a little. Even among the true popcorns there is a wide variation in the degree of popping. The ability to pop seems to be conditioned by the relative proportion of horny endosperm where the starch grains are embedded in a tough, elastic colloidal material, which confines and resists the steam pressure generated within the granule until it reaches explosive force.[1] Some varieties of sorghum with seed of a dense flinty structure, such as Pink kafir, pop very well. Manufacturers of breakfast cereals have perfected mechanical methods of confining steam pressure within grains until it is suddenly released, when they puff or pop to several times their original volume.

DISTRIBUTION, VARIETIES, AND DESIRABLE QUALITIES

COMPARED with dent corn, popcorn is a relatively minor crop. Only about 0.1 percent of the total corn acreage of the United States ordinarily is occupied by popcorn. It is grown almost solely for human consumption as freshly popped corn or as a basis of popcorn

[1] WEATHERWAX, P. THE POPPING OF CORN. Ind. Acad. Sci. Proc. 1921: 149–153. 1922.

confections. It has approximately the same chemical analysis and the same feeding value as dent corn. Thus, popcorn may be substituted for dent corn as feed for livestock if occasion demands, although the lower acre yield and the hardness of the endosperm, which necessitates grinding, make it uneconomical to do so under ordinary circumstances.

It is probable that popcorn is grown as a family garden crop for home consumption in every State in the Union. A very considerable proportion of the total popcorn production is represented by these small growers whose crop is used in the home or is sold only locally. A multitude of varieties, colors, and types of popcorn are used for this purpose.

Commercial production to supply vendors, manufacturers of popcorn confections, and the general retail grocery trade has been highly specialized and localized until the last 2 or 3 years. Sac and Ida Counties in western Iowa have been the principal center of commercial popcorn production. Valley County in central Nebraska and four or five counties in northeastern Kansas have also been important in commercial production.

Very recently Iowa, Nebraska, and Kansas seem to have been somewhat less important as centers of commercial production. This has been due in part to a changing demand, which in recent years has favored varieties too late to mature satisfactorily in northern regions, but more largely to the unprecedented series of disastrous droughts during the last few seasons that have centered around the traditional commercial popcorn region. As a consequence of crop failures, popcorn prices have been abnormally high, and therefore scattered growers in many localities outside the worst of the drought area have found popcorn growing very profitable during the years when the total production of the country was at a low ebb. Whether the present distribution will continue during years of normal production is a question for the future which only the complex interaction of economic and agricultural factors can decide.

Although there are in existence innumerable types and varieties of popcorn, only five or six are of commercial importance. Until comparatively recently, White Rice, Jap Hulless (Japanese Hulless), and Queen Golden were the chief varieties used. The variety of popcorn called South American, which was introduced some 15 years ago, increased rapidly in favor in the popcorn trade and soon became a serious competitor of the other varieties. The large size of the kernel, its yellow color, and its peculiar "mushrooming" characteristic in popping seemed to catch the public fancy enough so that its toughness and mediocre quality were largely overlooked. An old variety renamed Spanish popcorn was in vogue for a few years, because the large size of its kernels and its ability to withstand processing fitted it admirably for the manufacture of caramel confections. A small-kerneled, smooth, yellow variety of high popping expansion, known variously as Supergold, Sunburst, or Yellow Pearl, also has become of commercial importance. The old Queen Golden corn has now been almost entirely displaced by South American and Supergold, its yellow competitors.

In popcorn the desirable characters to be achieved by the breeder include all of the attributes of a good variety of dent corn, and in addition must include high expansion and tenderness. Fortunately,

high popping expansion and tenderness of the popped kernels seem to be closely correlated, so that in attaining high popability one also is very likely to have a tender product. The absence of a coarse hull and the presence of a good flavor are also desirable characteristics of the final product. Although most people ordinarily do not realize that there are distinctive flavors in various samples of popcorn, these are as characteristic as in different varieties of apples. Some strains have a noticeably sweetish flavor after being popped, some are practically tasteless, while others have a rather strong field-corn flavor.

High expansion in popcorn is dependent upon complete and normal maturity in addition to the inheritance of genes conditioning a dense and elastic endosperm. Since corn diseases usually interfere with normal maturity, it follows that selection for high popping expansion also tends to select for resistance to many of the common corn diseases, such as smut and the stalk and root rots. This is very fortunate for the breeder, since it is, of course, much easier to make improvements in a crop in which desirable characteristics are correlated than in one in which they tend to be mutually exclusive. In the case of popcorn there seems to be a sound basis for placing considerable emphasis on the individual ear-popping test, described later in this article.

METHODS AND RESULTS IN BREEDING

Mass Selection

Of the various methods of corn breeding that have been tried from time to time, that of mass selection alone has stood the test of time as of general application to improvement within open-pollinated varieties of corn without resorting to inbreeding. This is as true of popcorn as of dent corn. Mass selection lends itself particularly to the improvement of popcorn quality. As in field corn, mass selection in popcorn begins with field selection of a large number of ears from desirable plants when the crop is mature but before the first killing frost occurs. These ears should be dried quickly, but not so thoroughly as they would be for seed. About 14-percent moisture gives nearly maximum popping behavior and insures against loss of viability by freezing under any ordinary storage conditions.

After being numbered for identification purposes, the ears can be popped individually by shelling enough from one side of each to fill a small measure for the popping test. After popping, the volume of the product is measured in a suitable container so that the ratio of the volumes before and after popping may be obtained and recorded as the popping expansion. Unfortunately, a standardized method of testing has never been agreed on, so that comparisons of popping tests made by different people sometimes are misleading. In this laboratory ordinary glass graduates are used, as shown in figure 1.

For individual ear tests a popping charge of 25 cubic centimeters ordinarily is measured out in a small graduate, and the popped corn is later measured in a 1,000 cc graduate. Any convenient modification of this procedure that will give an accurate measure of the popping expansion would do just as well. It is highly important, however, that the tests of the various ears be made under as nearly comparable conditions as possible. The factors particularly to be guarded are:

(1) The moisture content of the ears must remain as nearly constant as possible for the duration of the tests, since moisture content has an important influence on popping expansion. (2) The conditions of popping, such as degree of heat used, absence from drafts, etc., should be the same for all tests. (3) A routine procedure in measuring the samples before and after popping should be followed, in order that the same degree of packing may be obtained for every sample.

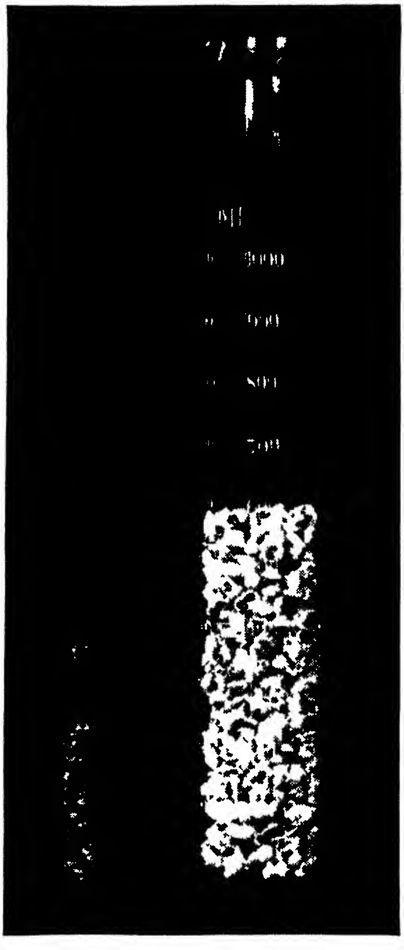

Figure 1.—Glass graduates used to measure the volume of popcorn before and after popping. A popping expansion of about 24 volumes (600÷25) is indicated in this sample.

When samples from a considerable number of ears from an apparently uniform variety are popped separately, striking differences in the popping expansion of the individual ears will be observed. Usually the best ears will show about twice the popping expansion of the poorest ones. The distribution of popping expansion of 1,152 individual ears taken from a small isolated plot in 1928 is shown in figure 2.

By using only the highest 10 or 15 percent of the selected ears for seed purposes a rather rigid selection on the basis of popping expansion can be made. In order to avoid the injurious effects of close breeding in an open-pollinated variety, care must be exercised not to limit too greatly the number of seed ears utilized to propagate the strain. Although it is difficult to set an arbitrary minimum, a mixture from not less than 50 ears should be used to plant the seed plot each year, and one from 100 or more selected ears would be much safer. In following a system of mass selection, the unpopped remnants of the most desirable ears are simply bulked together to furnish seed for an isolated seed plot the following year.

In contrast to the mass-selection method, the pedigree or ear-to-row method may be used, in which each row is planted from a single ear and a preliminary selection is made on the basis of individual rows, followed by selection within the row. It is probable that this method has no advantages over mass selection to counterbalance its disadvantages of more labor and greater likelihood of close breeding.

As in all selection work, there is a constant drag of regression toward the mean of the population in selection for high popping expansion.

Consequently, one may not expect the average popping expansion of the crop produced to be nearly so high as the average of the selected ears that are planted. If the work is carefully and consistently done, however, some progress in raising the mean is accomplished each time, and over a period of years real improvement may be effected, although such improvement may not be expected to continue indefinitely.

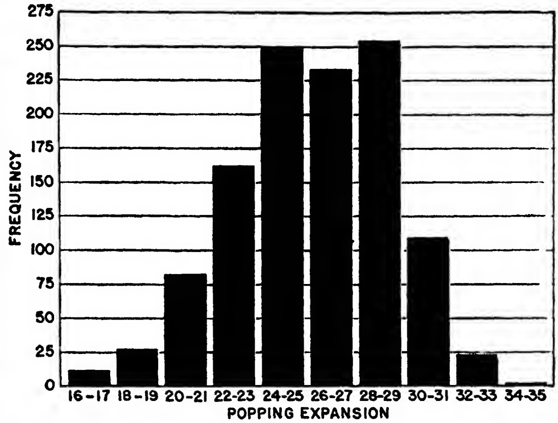

Figure 2.—Distribution of 1,152 individually popped ears of Supergold popcorn harvested from a small breeding plot. Note that the best ears had about twice the popping expansion of the poorest ones.

In an experiment conducted cooperatively by the Department and the Kansas Agricultural Experiment Station to test the efficacy of mass selection in popcorn breeding, the popping expansion was increased from 19 to 26 volumes in 6 years. Comparatively little increase in popping expansion has been effected since that time, which indicates that the practical limits of improvement have about been reached. This work was initiated by J. G. Willier, formerly assistant agronomist in the Bureau of Plant Industry. The resulting improved strain, originally known as Sunburst, but later changed to Supergold, has been distributed by the Kansas station.

Where some attempt at improvement of quality is desired, but where the labor of popping a large number of individual ears for seed selection is out of the question, a modification of the mass-selection method based on kernel structure may be used. A reasonably good correlation ($r = -0.59 \pm 0.022$) has been found [2] between the amount of soft white starch in the center of the kernel and the popping expansion of the ear from which it came. Since the correlation is negative, it means that the ears with the least amount of soft starch in the kernels will on the average pop the best. In selecting seed, three or four kernels from each ear may be split with a sharp knife to determine those with the least amount of soft white starch. These ears should be saved for seed. Although selection for high popability from kernel examination is much less desirable than from direct popping tests, it is much better for the maintenance of a good strain than no selection at all. It is particularly valuable as a means by which to cull out the traces of mixture with dent corn which tend continually to creep into popcorn varieties.

Popcorn Hybrids

Hybridization between inbred lines, the newest and most promising method of corn breeding, is equally as applicable to popcorn as to

[2] Willier, J. G., and Brunson, A. M. factors affecting the popping quality of popcorn. Jour. Agr. Research 35: 615–624, illus. 1927.

dent corn or to sweet corn. A general discussion of corn breeding appears in the 1936 Yearbook of Agriculture,[3] in which the methods and results of hybrid corn production are fully described. With the exception that popping expansion and eating quality must be given paramount consideration in popcorn, the technique followed is the same as for field corn. The possibilities are fully as promising, but thus far comparatively little work has been done in the production of popcorn hybrids.

The only hybrid popcorn known to the writer that has been released for commercial production is Minhybrid 250, from the Minnesota Agricultural Experiment Station. Inbreeding of 200 to 250 lines of Michigan Pop, a selection of Jap Hulless, was begun in 1925 by H. K. Hayes and H. E. Brewbaker. Since 1930 the breeding work has been done by H. K. Hayes and I. J. Johnson. The original lines were culled severely on the basis of agronomic characteristics, so that when the first crosses were made in 1929 only seven remained. These seven inbreds were combined in all possible combinations of single crosses and tested thoroughly during the 4 years 1930–33. On the basis of these trials, single cross C–1 × C–6 was selected as the best combination and named Minhybrid 250. Representative ears of inbreds 1 and 6 and of the single cross are shown in figure 3. The component inbreds were distributed in 1934, and small commercial acreages have been grown in 1935 and 1936. As an average of 3 years' tests at University Farm, Minhybrid 250 has produced 16 percent higher yield and 29 percent higher popping expansion than the standard open-pollinated Jap Hulless used as a check. The adaptation of this hybrid seems to be limited to central Minnesota. In a trial in the southern part of the State the hybrid was much less satisfactory.

In 1931, the Minnesota station also started inbreeding a group of lines from Burbank Pure Gold, a 10-rowed yellow pearl variety. These inbreds are now just ready for top-cross tests and trials of recombination.

At the Iowa Agricultural Experiment Station J. C. Eldredge began inbreeding in 1928 with 50 ears of Jap Hulless, part of which were selected from a mass selection plot of the previous year and part from various commercial growers. These lines have been culled to about 20 inbreds between which combinations have been tested during the period from 1933 to 1936. On the basis of these tests the most promising hybrid seems to be a three-way cross which has averaged about a 20-percent increase in yield and a 20-percent increase in popping expansion over the open-pollinated Jap Hulless used as foundation material. An extensive State-wide test of this hybrid is planned for 1937. No distribution for commercial production has yet been made from Iowa.

In 1933 a new group of inbreds from Jap Hulless, South American, and Supergold were started at the Iowa station, which are still in the developmental stage.

In 1923, J. G. Willier, of the Bureau of Plant Industry, then at Washington, D. C., and later at Manhattan, Kans., in cooperation with the Kansas station, started inbred lines with a yellow pearl popcorn similar to Queen Golden. Later, C. W. Bower, also of this

[3] JENKINS, M. T. CORN IMPROVEMENT. U. S. Dept. Agr. Yearbook 1936: 455–522, illus. 1936.

Bureau, was associated with this work. This investigation was started mainly as an experiment to compare the efficacy of inbreeding compared with mass selection and ear-to-row breeding as a means of popcorn improvement Careful selection was practiced during the inbreeding period, both within and among the inbred lines, for

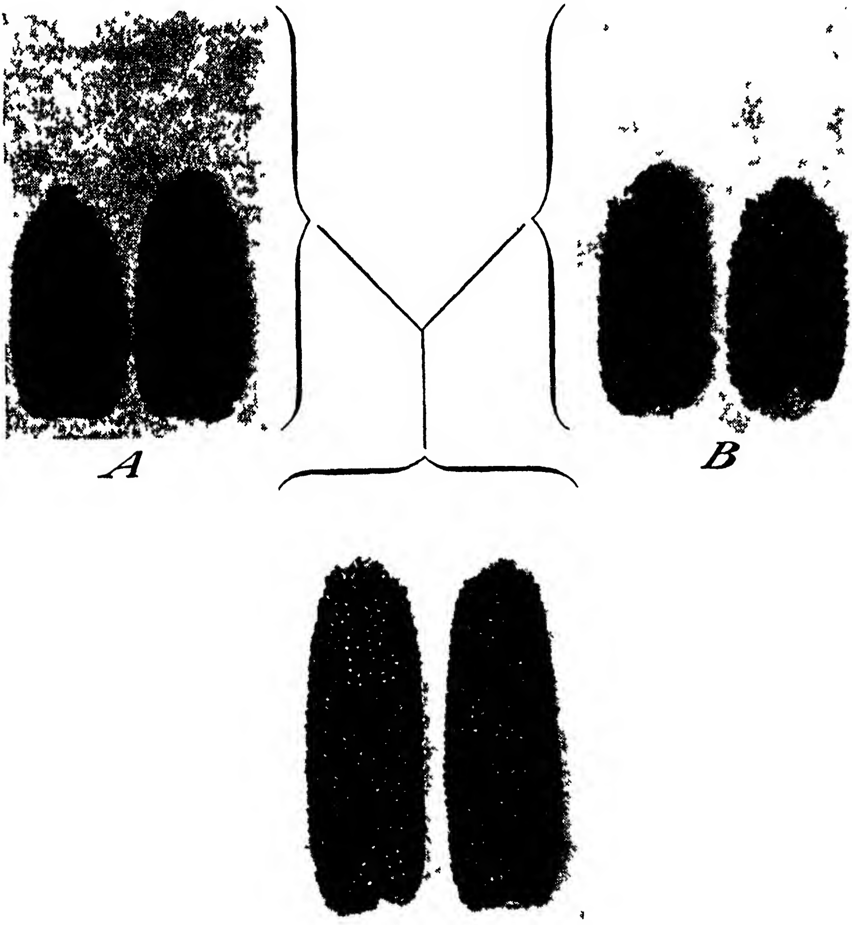

Figure 3.—Representative ears of the two component inbred lines and of the cross in Minhybrid 250· *A*, Line C-1; *B*, line C-6, *C*, Minhybrid 250.

popping behavior as well as for characters of agronomic importance At the conclusion of the work in 1931 it was found that hybrids much superior to the foundation material had been produced During the same period, however, marked improvement in the original variety had been effected by mass selection, as referred to earlier in this article, so that when the mass-selection strain was used as the basis of comparison the hybrids showed no superiority in popping expan-

sion, although somewhat higher yields and considerably greater uniformity of the crop were obtained.

New and much better inbred lines were beginning to be available from the strain already improved by mass selection, so it was decided to drop the original lines and wait until hybrids distinctly superior to existing open-pollinated varieties in popping expansion as well as in yield were available before commercializing them. Preliminary trials of hybrids from this newer material have been very promising, although the corn failures of 1934, 1935, and 1936 at Manhattan have greatly retarded the recent development of the work. In a cooperative field trial near Colfax, Ill., in 1935, 19 of 81 hybrids produced in Kansas had popping expansions of 25.0 volumes or more in comparison with an average popping expansion of 24.1 volumes for the parent stock, Supergold, grown in the same test. The highest popping expansion for any hybrid was 28.5 volumes. Yield was increased even more than popping expansion, the average yield of 72 of the 81 hybrids having uniform stands being 3,218 pounds per acre in comparison with 2,517 pounds per acre as the average of the Supergold checks. Unfortunately, the highest yielding crosses did not also possess the highest popping expansion, but a few were distinctly superior to the parent open-pollinated strain in both respects.

The difficulty of combining top yields and superior popping expansion in the same strain or hybrid of popcorn seems to be a common experience. Apparently the genetic constitution necessary to produce extremely high yields also produces too much soft starch in the centers of the kernels for best popping results. Why this is so is not definitely known. Perhaps the plant is unable, with the plant food materials at hand, to produce more than a given amount of the colloidal matrix in which the starch granules are embedded in the horny portions of the endosperm, and when greater amounts of endosperm are produced, increasing proportions are left in the form of soft starch. If this be the case, the situation is roughly analogous to the difficulty of obtaining a dairy cow with maximum milk production and maximum butterfat content in the same individual. Whatever the causes, it has been the experience of the writer that some compromise must be made in either yield or popping expansion or both to secure the best all-round popcorn hybrids from the utility standpoint.

Less loss of vigor from inbreeding is experienced normally in popcorn than in dent corn. Because of the ability to find comparatively productive inbreds, and because of the small amount of seed required per acre, it probably will be possible to utilize single crosses largely in commercial production. The shape of popcorn kernels from inbreds is about the same as that from their parent varieties, and the size is usually but little smaller, so that no mechanical difficulties with corn planters are encountered in using seed grown on inbred lines in the production of single crosses. The commercial use of single crosses simplifies hybrid seed-production problems and makes possible a most uniform market product.

In the limited trials thus far made, popcorn hybrids between inbreds from different varieties have given the most outstanding increases in yield. This confirms the experience with dent corn hybrids, where crosses between entirely unrelated stocks in the main have been

most successful. Hybrids between inbreds of Supergold and South American have given some extremely high yields, but the tendency toward a negative correlation between yield and popping expansion, referred to above, has seriously limited the usefulness of most individual crosses of this group. A very unusual situation is encountered in crossing South American and Supergold, in that the combination is perfectly fertile when South American is used as the pollen parent, but is almost completely sterile when Supergold is used as the pollen parent. Utilization of hybrids involving this combination must therefore be planned so that Supergold may serve as the seed-producing parent. Demerec[4] reports a similar case of sterility in popcorn, although the varieties involved and the source of material are not clearly stated.

Synthetic Varieties

One variant of the inbreeding method, which has interested corn breeders for some time, is the possibility of recombining a fairly large number of selected inbreds into a synthetic variety that might be better than the original variety and which, because of the number of component lines, could be continued by open pollination without serious reduction of vigor and yield. Starting about 1920 with observational plots and yield tests of all available popcorn varieties, J. R. Duncan, of the Michigan Station, has selected Australian Hulless, Japanese Hulless, Japanese Dwarf Rice, and Queen Golden as the most promising varieties for his conditions and has started inbred lines within these varieties. It is planned to recombine the best inbreds into two synthetic varieties, one within the hull-less group and one within the yellow pearl group. Although in field corn no synthetic variety of outstanding yielding ability has yet been produced, it should be possible, by rigid selection of the inbred lines on the basis of popping expansion, to produce in popcorn a synthetic of high quality. No results of the Michigan experiment are as yet available, but its progress is being watched with interest.

Breeding for Resistance to Diseases and Insects

Resistance to disease is an important consideration in popcorn breeding. Any parasite that saps the vitality of the plant or prevents complete and normal maturity of the grain tends to lower popping expansion. Moreover, the diseases generally grouped as the ear rots are particularly objectionable, since occasional moldy kernels are very undesirable and are practically impossible to separate from corn after it is shelled. The majority of commercial popcorn dealers and processors sort the corn by hand before it is shelled, in an attempt to eliminate diseased ears. Frequently, however, portions of ears with early stages of infection are not easily recognized, and although such corn frequently will pop, it has distinctly undesirable flavors.

No project dealing specifically with breeding for disease resistance in popcorn is known to the writer, although in practically all work, both with open-pollinated varieties and with hybrids, attention is given to freedom from diseases as one of the bases of selection. In the many field-corn hybrids produced experimentally from which the

---

[4] Demerec, M. cross sterility in maize. Ztschr Induktive Abstam. u Vererbungslehre 50: 281-291. 1929.

commercial hybrids now in production represent a small and highly selected portion, there has been marked variation in quality. It is likely that just as wide a range of disease resistance will be found in popcorn hybrids. Some of the experimental popcorn hybrids referred to above are very distinctly superior to open-pollinated varieties in freedom from diseases.

Insect damage also is very objectionable in popcorn and is severely discriminated against by the trade. Corn earworms are the cause both of direct damage to the grain and of indirect damage through secondary infestations by other insects and infections with ear rots. Injury by the corn earworm and by storage insects is particularly severe in the Southern States, where it is a serious problem, especially in popcorn, which is used primarily as human food.

At the Texas Agricultural Experiment Station, P. C. Mangelsdorf is attempting to combine the superior resistance of some southern varieties of field corn with the popping ability of popcorn. Of the varieties tried, Yellow Creole has given the most promise of transmitting insect resistance without interfering with popability. By means of a series of crosses, backcrosses, and recombinations coupled with rigid selection, progress is being made and hopes are entertained that a desirable popcorn may result that will be resistant to grain injury by insects.

GENETICS AND CYTOLOGY

THE genetics and cytology of popcorn are the same as for other subspecies of *Zea mays*. These subjects have been discussed in the article already referred to in the 1936 Yearbook of Agriculture,[5] to which attention is directed for detailed information. As a matter of fact, many of the testers used in unraveling the linkage relations in corn have been popcorns or popcorn derivatives. Popping behavior is unquestionably a heritable character, but it is probable that it represents one of the more complex cases of quantitative inheritance conditioned by many genes.

BREEDING AND GENETICS IN POTATO IMPROVEMENT

F. J. STEVENSON, Senior Geneticist,
C. F. CLARK, Horticulturist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

WHEN the Spaniards invaded South America they found a large number of varieties and species of potatoes under cultivation, the tubers of which were used as a common article of food by the natives. Where these varieties and species originated is not well known, but they seem to be native to the American Continent, since their relatives are still to be found growing wild on the elevated regions extending from the southwestern part of the United States to the southern part of South America, particularly on the higher altitudes in Bolivia and Peru and the coastal regions and nearby islands of southern Chili. All the species seem to require a cool climate, since they are found growing at high latitudes in regions near the Equator and none is known to occur under tropical conditions.

INTRODUCTION INTO EUROPE AND NORTH AMERICA

IF THE origin of the potato is uncertain, its introduction into Europe and North America is also shrouded in mystery. Many interesting legends have been written concerning this, but few reliable facts are available. It is not hard to believe that the Spanish sailors, on their return from their many trips to the New World, brought back potatoes and introduced them into Spain and Portugal. That these were the common potato known today and not the sweetpotato is proved definitely by a report of Clusius published in his Rariorum Plantarum Historia in 1601, giving an illustration and description of a plant sent him in 1588 by the Governor of Mons. The flowers were light purple and the original plant obtained by Clusius produced a fruit ball and two reddish tubers. From Spain and Portugal the potato was taken probably to Italy, from there early in the seventeenth century to Austria, then to Germany, from Germany to Switzerland, and finally to France. The legends surrounding the introduction into Ireland have a more romantic setting. They are centered around Drake, one of Queen Elizabeth's pirates, who was encouraged by the Queen to plunder Spanish ships and Spanish possessions. It is supposed that on one of these trips Drake obtained potatoes in the West Indies for his ship's stores and that some of these were carried to Ireland about 1586.

Little is known of the introduction of the potato into North America. It is generally believed that the English colonists of Virginia and Carolina obtained the potato from Spaniards or from other travelers. The most authentic report shows that potatoes were first grown in this country at Londonderry, N. H., in 1719, from stock brought from

Ireland. It was for this reason, no doubt, that the potato was called the "Irish" potato. The name is still used, especially in the South, where it serves to distinguish the potato from the sweetpotato.

Most of the stories of the introduction of the potato into Europe and North America are no doubt legendary, as well as some of the tricks that were supposed to have been adopted to get people to use the tubers for food. The spectacular increase of the potato as a food crop, however, is not legendary, but is one of the miracles of agriculture. Although it is only a little over 300 years since the first introduction into Europe and about 200 years since the first importation into the United States from Ireland, the potato is now grown in almost every important agricultural country in the world. The crop for the United States and Canada for 1934–35 was nearly half a billion bushels, and the total for the world, not including the Union of Soviet Socialist Republics and China, for which no data are available, had reached the stupendous figure of over 6 billion bushels.

BOTANICAL RELATIONSHIPS

THE potato belongs botanically to the section *Tuberarium* (*50*)[1] of the genus *Solanum*, the members of which are, with few exceptions, tuber bearing. This section comprises not only the cultivated forms but many wild species. Since it is probable that undiscovered species occur in regions not yet explored by botanists, the total number cannot be definitely stated, but it is believed to exceed 100.

[1] Italic numbers in parentheses refer to Literature Cited, p. 434.

MILLIONS *of dollars are spent each year in providing ways and means of protecting the potato crop from diseases, and these colossal efforts have done their part in providing the consumer with potatoes fit for consumption; but in spite of them, many millions of bushels are lost each year. The annual loss from late blight alone has averaged 9,000,000 bushels for the past 10 years. Thus disease resistance has been a major objective in the well coordinated national potato-breeding program now being conducted throughout the United States, in which the Department of Agriculture and all interested States closely cooperate. Already many varieties have been obtained resistant to late blight, to scab, and to two of the mosaic diseases. The results indicate that by using genetic principles as a working tool, it should be possible to solve many if not all of the disease problems of potato growers by combining resistance with superior qualities of economic importance, such as shallowness of eye, desirable shape, good cooking quality, high yield, and adaptability to local conditions.*

Considerable confusion has existed in the past in regard to what has been considered the species *Solanum tuberosum* L., which has generally been understood to comprise all cultivated varieties of potato. These have recently been assigned by Bukasov (*9*) to 14 species. According to his classification, *S. tuberosum* includes the Chilean cultivated forms as well as the commercial varieties of North America and Europe, which he believes to be of Chilean origin. Most of the common cultivated varieties of the Andes region are placed in the species *S. andigenum* Juz. and Buk. The 12 remaining species are grown in small local areas in the Andean countries and more or less resemble the wild species in their general appearance. It is doubtful whether any of the cultivated varieties of Europe and North America as known today have been derived from them.

EARLY IMPROVEMENT IN THE POTATO

There is little information available regarding the source of the potato stock grown during the first 100 years after its introduction into the United States. It is believed that not many new varieties of importance were produced during that period. During the second century of potato culture in this country, however, there was great activity in the production of new varieties. Data reported on 228 of these varieties show that they originated in 21 States. New York and Vermont, however, produced 50 percent of the total number. Of the 160 varieties whose date of origin is known, 80 percent were produced during the 40-year period 1861 to 1900 and 48 percent during the two decades 1871 to 1890 (*12*).

The most important varieties produced during this 100-year period and their originators, as reported by Stuart (*71*), are given in the appendix.

Special mention should be made of C. E. Goodrich, as his work was the first to produce lasting results. He believed that the disastrous epidemics of late blight during the years 1843–47 were the result of a reduction in the vigor of the plants caused by long-continued propagation by vegetative means and that this vigor could be restored by growing plants from true seed. While he did not succeed in the control of late blight by this means, he may be considered to have laid the foundation of potato breeding in this country by furnishing material to be used by other breeders. The ancestry of 170 varieties can be traced back to Goodrich's Garnet Chili, a seedling of the imported Rough Purple Chili. They include several of the well-known varieties of commerce, such as Beauty of Hebron, Burbank, Early Ohio, Early Rose, Green Mountain, Prolific, and Triumph.

The work of Pringle, as recorded by Stuart (*71*), is outstanding in that it represents what is believed to be the first systematic effort to obtain seed by controlled hybridization. This seed was not only used for the production of the varieties he introduced but was disseminated to others through his contract with a seedsman in New York to furnish hybridized seed at $1,000 a pound.

Many varieties of excellent quality and high yielding ability, which were the principal objectives, were produced during this period. The work, which made important contributions to the agriculture of this

country, was carried on entirely by private agencies rather than by public institutions. Most of the men engaged in the early work were practical potato growers, except C. E. Goodrich, who was a clergyman, of Utica, N. Y., and E. S. Carman, who was editor of the Rural New Yorker.

PRESENT-DAY PROBLEMS

The commonly grown commercial varieties of potatoes differ from one another in earliness, tuber shape, adaptation, depth of eye, cooking quality, and yielding ability. In certain of these characters, such as yielding ability, some of these varieties have reached a high standard of excellence when grown under conditions to which they are adapted. These same varieties are, however, poor in other characters. Some are not adapted to a wide range of conditions; others have deep-eyed tubers, which cause waste in preparing the potatoes for cooking. All are susceptible to one or more of the common potato diseases, including the virus diseases, late blight, common scab, fusarium wilt, rhizoctonia, early blight, and blackleg. Control of these diseases requires a continual fight on the part of the potato grower and adds greatly to the cost of producing the crop.

The group of diseases caused by viruses are perhaps the most widespread and the most baffling. In this group are found mild mosaic, latent mosaic, leaf roll, spindle tuber, and yellow dwarf. These diseases occur in every potato-growing region of the United States, and it is probable that not a single field could be found entirely free from them. They are not new. Their effects have been observed by growers for many years, but for a long time it was thought that they were due to "running out" or "degeneracy", brought about by growing potatoes year after year from the same tuber stock. It is only a few years since it was discovered that these troubles are due to virus diseases. It was soon observed that some varieties did not "run out" so quickly as others, or, as we now say, some varieties are more resistant to the attacks of certain viruses than others. Knowing that such differences must have a genetic basis, breeders are working to obtain resistance to these diseases in combination with other characters of economic importance.

Late blight, caused by *Phytophthora infestans* (Mont.) DBy., adds more to the cost of producing the potato crop than perhaps any of the other diseases. The losses from this disease alone have been more than 9 million bushels a year for a period of 10 years, according to estimates issued by the Division of Mycology and Disease Survey, Bureau of Plant Industry, United States Department of Agriculture. In some seasons and in certain localities the disease causes very little damage. At other times (as in 1927, 1928, 1932, and again in 1936) large losses are sustained by growers. The heaviest loss for any one year, nearly 31 million bushels, was reported in 1928. That year late blight was reported in 15 States, with the loss in New York estimated at approximately 13 million bushels. In 1932 the reduction of the crop was estimated at 9,230,000 bushels, the greater part of which, 9,058,000 bushels, was reported from Maine. Again in 1936 heavy losses occurred in Maine.

It is true that late blight can be controlled to a large extent by careful spraying with bordeaux mixture, but despite the fact that

control measures are being practiced more generally than ever and that spray equipment has been improved and spray programs have been more faithfully carried out, large losses continue to occur, not only from reduction in yields but also from interference with marketing operations. Rot may develop on infected tubers in storage and in transit. Because of the uncertainty involved, the buyer is reluctant to purchase potatoes for storage purposes. There is considerable expense every time a carload is regraded at a terminal market, and this happens frequently in blight years. These losses all affect the grower.

Common scab, caused by *Actinomyces scabies* (Thax.) Gues., is another disease that takes a toll from the grower. The organism causing this disease lives over in the soil and is also carried on the tubers. Treatments have been recommended that will kill the organisms on the tuber, but no one has yet devised a method to fully protect the growing tubers from the soil-borne organisms.

Millions of dollars are spent each year in providing ways and means of protecting the crop from the attacks of these and other diseases, but comparatively little attention has been paid to obtaining varieties resistant to the attacks. The colossal efforts in the way of plant protection have done their part in providing the consumer with potatoes fit for human consumption, but in spite of these efforts millions of bushels of potatoes are lost each year. Results already obtained indicate that by using genetic principles as a working tool it should be possible to solve many if not all of these problems by producing new varieties in which resistance to various diseases is combined with other characters of economic importance, such as shallowness of eye, desirable shape, good cooking quality, and high yield.

In the production of such varieties the plant breeder must be familiar with the local problems of growers; he must have a knowledge of the existing varieties and the important economic characters of each; and he must be familiar with the botanical structure and behavior of the various parts of the growing plants. A knowledge of the modes of reproduction with the advantages and limitations of each is the first essential.

REPRODUCTION IN THE POTATO

The potato plant is reproduced in two ways. In commercial practice it is grown from tubers, a method of vegetative or asexual reproduction. Plants can be grown from true seed, however, by sexual reproduction.

Asexual Reproduction

A number of mutations in the vegetative cells of potatoes have been studied and described, but they are too few and far between to be relied upon in a breeding program as the only source of variation. In many cases, too, the changes are of minor importance. Clark (*13*) has described several mutations that have occurred in the color of the skin and of the eyes. Salaman (*57*) classifies mutations of this sort according to whether they are due to the acquisition or to the loss of a character and whether they affect the tuber only or the whole plant. Mutations due to the loss of a character are by far the most common. There are a number of instances where the red tuber loses part of its

color and becomes "splashed", or loses all of its color and becomes white. Purple tubers may become red, purple splashed, or white. Somewhat similar changes have been observed for flower color. Mutations due to the acquisition of a character, which might be called positive mutations, are much rarer. Examples are a red-tubered sport from a white-tubered variety, or a fully colored one from a partially colored variety. Mutations occurring in more than one character in the same individual are extremely rare. Mackelvie (*38*) reports such a case in which there was a white-tubered mutation combined with a different leaf shape from that of the parent variety. The

Figure 1.—Potato plants grown from true seed in the greenhouse. These plants have been transplanted from the germination pots to individual pots where they will be grown until they are transplanted in the field.

leaflets of the mutant were narrower and more pointed. The yield was reduced also.

East (*22*) carried out some rather carefully controlled studies on the occurrence of somatic or vegetative mutations in the potato. In these studies each variety was started from a single hill. During the course of the study five permanent changes from pink to white tubers, two permanent changes from long to round tubers, and four instances of changes from shallow to deep eyes were observed. Selection for high nitrogen content gave negative results.

Clark (*16*) made a study of six commercial varieties to determine whether their origin could be accounted for by mutation. The methods employed were those reported by Asseyeva (*1*) for this purpose. They consisted of removing from the eyes of the seed pieces

the outer layers of tissues, which, in skin-color mutations, are the mutating tissues. This allowed the sprouts from which the plants under test were grown to develop from the deeper layers, the original unchanged tissue. Clark found that four of the varieties studied were mutations in the outer layers of the tuber. Two were mutations from smooth skin to russet skin, the third was a mutation from colored to colorless skin, and the fourth from colorless to colored skin.

That the occurrence of such mutations has not been an important factor in the development of potato varieties is shown by Clark (*12*), who reported that of 380 varieties that have originated in the United States and have at one time or another been introduced to the commercial trade, 306, or 93.3 percent, were of seedling origin, and only 22, or 6.7 percent, were reported as so-called sports or mutants. Of the 22 varieties reported as sports, 4 are white-tubered from varieties with colored tubers, and 4 are late-maturing variations found in early varieties. The meager information regarding the other 14 furnishes no basis for determining whether they were actual mutations or mixtures carried in the seed stock or volunteers that had persisted in the soil from some preceding crop.

Even if only a few varieties have arisen as the result of somatic mutations, they are still a source of variation that cannot be ignored entirely by the breeder.

Since it is quite impracticable for the plant breeder to make much improvement by selecting tubers of a variety with the hope of getting something new, he has to resort to the use of seed as a means of inducing variations.

Sexual Reproduction

As has been shown by Clark (*12*), most of the varieties that have originated in the United States were produced by growing plants from true seed (fig. 1). Salaman (*55*), discussing the production of new varieties from the same source in England, states: "It is by this method that practically every variety which has ever been raised since the introduction of the potato in 1588 has been attained."

True seed is a product of sexual reproduction and is found in the fruit or ball, which is quite similar to a small tomato (fig. 2). Under certain conditions these fruits are produced in abundance on some varieties but are rarely if ever seen on others. They are the result of the maturing of the flower, and each of them may contain 200 seeds or more.

The flower of the potato is what is known to botanists as a complete flower with calyx, corolla, stamens, and pistil. There are usually five stamens surrounding the pistil. The process of pollination is very simple because of the simple structure of the flower parts. Pollen may be brought to the stigma of the pistil in several ways. In varieties in which the pistil is the same length as the stamens or shorter, the mature anthers may come in direct contact with the stigma. When the pistil is longer than the anthers, pollen may fall upon it when the flower droops over, as it frequently does at the end of the day. Insects may be responsible for a much greater amount of cross-pollination than is commonly supposed; in some localities bumblebees and honeybees are often seen visiting potato flowers. Pollination may be effected also by the manipulations of the plant breeder.

The technique of cross-pollinating potatoes by hand is comparatively simple, but since relatively few varieties produce viable pollen, the setting of seed is often very small in amount. If a variety producing viable pollen is used as the female parent, the flower must be emasculated, that is, the anthers must be removed. This must be done before the anthers are mature, or the flower will be self-pollinated. Generally speaking, the anthers should be removed before the pistil protrudes through the bud, or a day or two in advance of the opening of the flower. A pair of sharp-pointed forceps is the only instrument necessary. All the flowers in the cluster that are in the right stage of maturity are emasculated, all others are removed, and the inflorescence is enclosed in a 1-pound paper bag, which is securely tied on. If the variety used as the female parent does not produce viable pollen, it is not necessary to emasculate before pollinating.

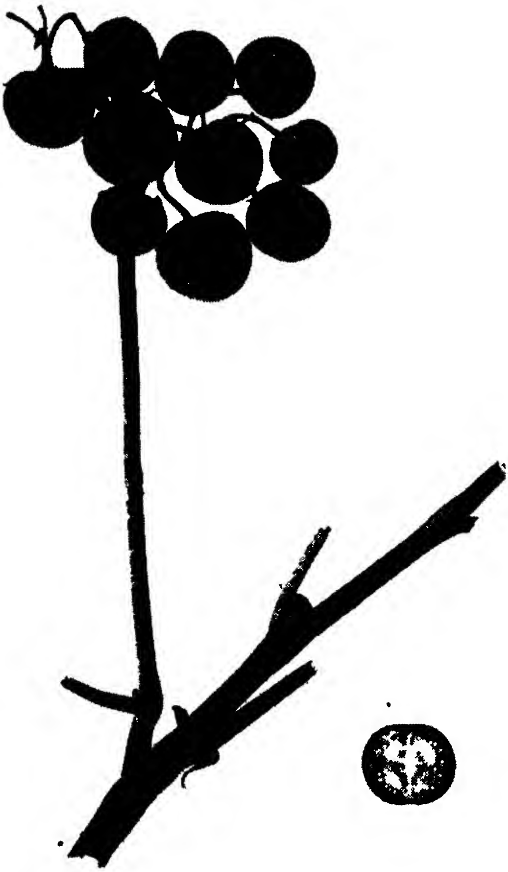

Figure 2.—Potato seed balls, the result of natural pollination of a variety that produces fertile pollen.

In pollinating, flowers with anthers ready to open are obtained from the male parent. These are placed on the thumbnail and the anthers are tapped gently with the forceps. The stigma of a seed parent is then gently rubbed in the pollen on the thumbnail until it is completely covered (fig. 3). The treated flowers are covered with the paper bag again. It has been found best to enclose as much foliage with the flowers as possible, to protect them from injury and to supply moisture; otherwise the flowers may dry up and fall off. The failure or success of the fertilization can be determined within a week or 10 days (fig. 4). As soon as the seed balls develop, the paper bags are removed and replaced by a cheesecloth sack, which is tied securely to the vines

Every breeding method has its advantages and limitations, and which one or which combination is used depends to a large extent on the problem involved in a particular case. The potato breeder today uses (1) the introduction of new varieties or species, (2) selection of clonal lines, (3) varietal crossing, (4) sib mating (brother-sister mating), (5) backcrossing to parental lines, (6) selfing and recombining selfed lines, (7) outcrossing to unrelated lines, (8) strain building, and (9) crossing of different species.

Since a discussion of these steps and methods involves a number of rather technical points, it will be postponed until later in this article,

Figure 3.—Pollinating potato flowers.

after the work now being done in potato breeding in the United States has been outlined.

THE NATIONAL POTATO-BREEDING PROGRAM

Because of the effect of environment on the fruitfulness (seed production) of potato plants, it is difficult, if not impossible, for many of the State experiment stations interested in some aspect of potato-breeding work to produce true seed. This would prevent the application of genetic principles to breeding problems and close the most promising avenue for their solution. Certain Northern States and other States with mountainous regions where potatoes can be grown at high elevations are especially favored, since true seed of many strains and varieties, as well as tubers of good quality, relatively free

from disease, can be produced in such places. In potato breeding, then, more perhaps than in any other breeding project, it is necessary that the interested States cooperate in their attacks on the many problems involved.

Organization of the Work

Since problems and objectives in potato breeding often cut across State lines and involve large regions of the entire country, the breeding work has been organized as a national project with all the interested State experiment stations and the United States Department of Agriculture cooperating. A number of the cooperating stations are

Figure 4.—Seed balls 8 days after the pollination operation shown in figure 3. These fruits are the source of seeds from which new varieties are produced.

now carrying on complete breeding programs—that is, they are able to produce true seed and raise seedling progenies for genetic analysis of the material they are interested in, and at the same time to produce improved varieties. The States of Minnesota, North Dakota, Michigan, New York, Louisiana, and North Carolina and the Department working in Maine and Colorado are at present producing true seed. If any of these find they can use more seed than they are able to produce, a supplementary supply is sent from Maine, Minnesota, or Colorado, or from any other State that has a surplus. True seed is also sent to other States not able to produce their own, such as Iowa, and in 1936, Nebraska and Wisconsin. The last two States have recently undertaken complete potato-breeding programs.

A number of States that do not grow potato seedlings test the most promising seedling varieties produced by others. New introductions,

parent material, and tubers representing seedling progenies are distributed to any State experiment station that can make use of them. The Department has been active in the production and distribution of such material and by common consent of the cooperators has been designated as the coordinator and clearing house for the project as a whole. A brief outline of the work carried on at the various stations under this project follows.

For a number of years the Department workers have been carrying on an intensive program of potato breeding at Presque Isle, Maine, in cooperation with the Maine Agricultural Experiment Station. As a part of the national potato-breeding program they are now engaged in (1) the production of true seed for use at Presque Isle and for distribution to other cooperating experiment stations; (2) distribution of single-tuber selections of various progenies to cooperating stations; (3) distribution of named and numbered seedlings for tests at other stations; (4) yield trials; (5) disease-resistance tests, including resistance to mild mosaic, latent mosaic, spindle tuber, leaf roll, late blight, and common scab; (6) genetic and cytological studies; and (7) the production of early-maturing varieties. In all this work higher market and cooking quality are being considered.

The work at the United States Horticultural Station, National Agricultural Research Center, Beltsville, Md., is interwoven with that carried on at Presque Isle and at other stations included in the national potato-breeding program. Two of the important aspects of the work at this station are the production of seedlings and the testing of seedling progenies and parents for resistance to virus diseases such as mild mosaic, latent mosaic, leaf roll, and spindle tuber. Tests are also made in the greenhouse for resistance to late blight and to the attacks of *Fusarium eumartii* Carp. and in the field for resistance to *F. oxysporum* Schl. Resistance to blackleg is being studied in certain progenies.

Iowa produces seedling progenies from seed furnished from Maine and Minnesota and tests the promising material produced by other cooperating States for its adaptability to Iowa conditions.

Louisiana produces some of the seed used in the production of seedling progenies. Other seed and material are supplied by Minnesota and the Department. Resistance to various diseases and adaptability of potato varieties to southern conditions are being emphasized.

The work in Michigan consists of growing seedling progenies, testing Department seedlings and those produced by other cooperating stations, increasing new varieties, carrying on disease-resistance studies with special reference to yellow dwarf and common scab, and producing early varieties with better market and table quality and varieties more suitable for muck soils.

In Minnesota securing resistance to virus diseases and to common scab in combination with early maturity is the main problem. A study of inbreeding and the recombinations of inbred lines is being carried on, and also a study of the cytological behavior of species hybrids.

In New York (Cornell University) resistance to late blight, using an immune wild species as the parent from which to obtain resistance, is one of the objects of the breeding work. Tests for resistance

to streak and leaf roll are being conducted. A much enlarged program is just now getting under way, which will emphasize market quality, cooking quality, adaptability, and resistance to a number of diseases other than late blight.

In North Carolina the work consists of the production and testing of seedling progenies produced at Raleigh and the testing of the most promising material grown at other stations. The emphasis is being placed on earliness and on resistance to disease and to leafhopper injury.

North Dakota produces some true seed but is supplied for the most part from Presque Isle, Maine. Varieties as early as Irish Cobbler but smoother and higher yielding are being sought.

The Department workers at Greeley, Colo., are attacking the problems of resistance to wilt, to psyllid yellows, and to common scab in relation to other characters of economic importance.

In Nebraska potato-breeding work has only recently been started. Earliness, yield, quality, and resistance to diseases will be emphasized. To begin with, resistance to fusaria is being studied.

In Wisconsin a complete breeding program has recently been undertaken. Studies of the breeding behavior of resistance to common scab and virus diseases, as well as of other characters of commercial importance, are getting under way.

In Charleston, S. C., at the United States Regional Vegetable Breeding Laboratory, breeding work recently initiated will deal with the problems of potato production in the coastal region of the Southern States, which center around yield, earliness, and drought resistance.

In Pennsylvania, at Drifton, a test project for potato wart resistance is conducted by the State Department of Agriculture in cooperation with the United States Department of Agriculture. A number of the most promising named and numbered seedling varieties are tested for resistance to this disease each year in soil infested with organisms that cause the wart disease.

In Florida, at Hastings, the Florida Agricultural Experiment Station has begun the study of resistance to brown rot in the potato in cooperation with the Department. A few varieties and seedlings have already been tested, and the experiment will be greatly enlarged in 1937.

In Indiana, Purdue University has recently initiated a program of breeding for disease resistance as a part of the national potato-breeding program.

In addition to the special problems enumerated above, the following States are cooperating to determine the adaptability of the new named and numbered seedling varieties produced by the Department or by any of the State experiment stations: California, Connecticut, Florida, Indiana, Iowa, Kansas, Louisiana, Maryland, Massachusetts, Minnesota, Michigan, New Hampshire, New Jersey, New York, North Carolina, North Dakota, Ohio, Oregon, Rhode Island, South Dakota, Tennessee, Virginia, Washington, and Wisconsin.

The cooperative potato-breeding work has not stopped at national boundaries, for material has been exchanged with a number of workers in Canada and other foreign countries.

Recent Results with Various Methods of Breeding

Clonal Selection

Progress has been made by the use of clonal selection in the State of New York. According to a recent unpublished report by J. R. Livermore, one of the cooperators in the national potato-breeding program, this method has been employed in connection with potato improvement work at Cornell University in cooperation with growers since 1905. Four varieties have been selected from the Smooth Rural (Rural New Yorker No. 2) and named. These are Heavyweight, No. 9, Pioneer Rural, and Toanco 4. A strain of Irish Cobbler has been named Pioneer Cobbler. Many other high-yielding clonal lines have also been selected from commercial varieties and are being produced by various growers. White-skinned bud sports from russet stock, the plant tops exhibiting heat resistance and the rugged vigor of the Russet Rural, have also been found. The Red Warba, one of the varieties recently introduced by the Minnesota Agricultural Experiment Station, occurred as a bud mutation from the Warba. This might be considered a clonal selection. By the method of careful selection within a variety or clon, not only are mutations uncovered but disease-free material is obtained, which in itself is justification for careful observation and selection.

Inbreeding and Recombination of Selfed Lines, Etc.

F. A. Krantz, of the University of Minnesota, another of the cooperators in the national potato-breeding program, has been placing greater emphasis than other breeders on the method of selection in selfed lines and recombinations between them. The results have been very similar to those found by the corn breeders, that is, selfed lines become homozygous and are less vigorous than the parent stocks from which they originated. Certain undesirable characters have segregated and been eliminated, such as short internodes, prostrate plants, simple-leaved types, chlorophyll deficiencies, and tuber abnormalities. Most important from the breeding standpoint, a number of self-fertile lines carrying desirable characters have been selected. In a brief unpublished summary of results to date, Krantz says:

> Selection in self-fertilized lines has been effective in establishing pollen fertility in combination with a wide variety of other characters. Used in combination with outcrossing it has facilitated the development of a large body of seed-setting material possessing selected germ plasm of the common varieties.
>
> The results show that it will be possible through this method gradually to combine the best germ plasm in the potato into a useful form for breeding purposes. The difficulties involved are the absence of information on the best selection technique and the necessity of developing one suitable for effectively selecting and combining desired characters. Pollen sterility at the outset also presented a serious problem since selection was restricted to the seed setting individuals. The difficulties mentioned are associated with potato breeding in general and are not specific to any particular method. Information is gradually accumulating on methods and technique of selection in inbred lines. The difficulty of maintaining and continuing inbred lines has been greatly reduced through selection for high fertility. Comparisons have been made and are in progress of varietal crosses, single crosses, three-way crosses, and top crosses to determine the relative hybrid vigor that might be expected from the different types of combinations. The inbred lines are valuable for their concentration of desirable characters in combination with pollen fertility, early maturity, upright sturdy vines, resistance to certain virus diseases, fine cooking quality, and varying rest periods.

Species Hybridization as a Method of Obtaining Late Blight Resistance and Frost Tolerance

Most of the attempts to produce blight-immune varieties of commercial value by the use of species hybrids have resulted in failure. Recently, however, Donald Reddick, of Cornell University, also a cooperator in the national potato-breeding program, has been getting promising results from such hybrids. For a number of years it had been known that certain forms of *Solanum demissum* Lindl. were immune to late blight. In 1928 Reddick began using hybrids between these and cultivated varieties in an attempt to combine this immunity with characters of the cultivated forms. Two years later the Department sent Reddick and three men from the Division of Plant Exploration and Introduction, C. O. Erlanson, Paul Russell, and M. J. Souviron, on an expedition to Mexico to find, if possible, more sorts of potatoes, either wild or cultivated, that might be resistant to this disease. A large number of collections were made. Among these several varieties of *S. demissum* were found to be immune and to have at the same time some frost tolerance.

In commenting on the methods and some of the difficulties that arise in this work, Reddick says:

> The object has been to get the blight immunity and frost tolerance of a wild plant into a plant of commercial value. Owing to sterility, incompatability, etc., the results thus far have been simply what could be got, not what it was planned to get. Efforts have been made from the beginning to determine the mode of inheritance of blight immunity and frost tolerance, but inability to obtain sets of seeds of the kind desired has prevented determining the mode. The original crosses are interspecific and involve hybridizing 72-chromosome plants with those having 48 chromosomes. Practically all of the crosses have had to be 48 male to 72 female, because the reciprocal cannot be effected. The second generation of such crosses does not segregate but "reverts" to the wild type. Repeated backcrossing eliminates most of the wild characters but blight immunity is transmitted.

This work has been in progress since 1928. Some of the families are progenies resulting from an original species hybrid between an immune species and a cultivated variety that has been backcrossed to cultivated varieties four successive times. Fifty percent of the progeny of the fourth backcross are immune to the late blight disease. As a result of this work Reddick has at the present time about 500 families of plants immune to late blight. Possibly 50 or more of these are approaching the commercial ideal as to size, color, shallowness of eye, heat tolerance, and date of maturity. They are still to be tested for yield, quality, and adaptability to various localities. A few of these families will stand at least four degrees of frost.

Results in Relation to Disease Resistance

Resistance to Virus Diseases

The potato breeders and pathologists of the Department, using the methods included in strain building (p. 429), are making real progress, both from the standpoint of scientific knowledge and of practical results in breeding for resistance to virus diseases. One variety produced, U. S. D. A. seedling 41956, is highly resistant if not immune to the virus of latent mosaic. It has been exposed to the disease in the field by being grown near other varieties known to have this

disease, and diseased stocks of other varieties have been grafted on the stems and on the tubers, but so far it has withstood every attack. A number of the progeny of a cross in which this variety was used as one of the parents show the same character, which indicates that immunity to latent mosaic is heritable. A number of other seedling varieties are resistant to this same virus in the field-exposure tests but contract the disease in tuber-graft tests, where it is expressed as top necrosis or death of the top of the plant. On the other hand, several attempts have been made to find even a single plant of Green Mountain free from this disease, but up to the present time such attempts have resulted in failure.

A large number of seedling varieties are highly resistant in the field tests to another virus disease, mild mosaic, perhaps the commonest of the "running out" diseases. These varieties have all contracted the disease, however, in the more severe tests of tuber grafting. In comparison with these resistant types, Green Mountain has been known to become 100-percent diseased with mild mosaic in the field exposure tests within a period of 3 years.

The fact that two virus diseases can be controlled by the production of resistant varieties gives hope that other virus diseases, such as spindle tuber and leaf roll, can be controlled in a similar manner. Comprehensive field-exposure and tuber-graft tests of a large number of seedlings and varieties are being made at the present time to determine whether any of them are resistant to either of these latter diseases. So far the results have not been encouraging. Although there have been a few escapes in the field-exposure tests, it is quite possible that none of the varieties so far tested is resistant to either of these diseases. Some of them may carry recessive factors for resistance, however, and many of them will be analyzed genetically to determine whether this is the case, and if it is, efforts will be made to combine the resistance with other characters of importance to the grower. In the case of leaf roll, a few recent introductions are reported to be resistant and will be used in future work. At the same time, the search in the United States and in foreign countries will be continued until types resistant to every virus disease are obtained or until all the possibilities for finding resistance are completely exhausted.

Resistance to Late Blight, Derived from Cultivated Varieties

Breeding for resistance to late blight was begun at a comparatively early date. In 1870 Darwin attempted through the use of species hybrids to produce varieties resistant to *Phytophthora*, but was evidently not successful. According to Stuart (*71*), the first American breeder to attempt the control of late blight by the introduction and production of blight-resistant varieties was Chauncey Goodrich, of Utica, N. Y., whose work has already been mentioned. This work was based on a small quantity of South American potatoes that he received in 1851 through the American consul at Panama. A number of other breeders made valuable contributions during the latter part of the nineteenth century, but with the exception of the work of Goodrich, resistance to late blight seems not to have been emphasized in the United States until potato breeding was actively undertaken by the Department in 1910.

According to Clark et al. (*18*), the only disease resistance sought at the time was to the late blight fungus. This work had not progressed very far, however, when it became evident that the virus diseases had to be given the chief consideration, and it was not until the present national potato-breeding program was under way that emphasis could be placed once more on breeding for resistance to late blight. Reddick, working in cooperation with the Department, had already undertaken the solution of this problem, using species hybrids. The Federal work at Presque Isle, Maine, and Beltsville, Md., includes the genetic analysis of the cultivated varieties to determine the possible existence of blight-resistant factors.

In 1932, when late blight caused the loss of over 9 million bushels of potatoes in Maine, 700 seedlings, representing 4 different progenies, and about 100 Green Mountain checks, were grown at Presque Isle in test rows of from 20 to 30 hills each. This plot, about 1½ acres in area, was not sprayed with bordeaux mixture but was sprayed in July with a single application of calcium arsenate to kill the Colorado potato beetle. Late blight infection was first observed on July 22. Conditions favorable for the spread of the disease prevailed during August, so that by the first week in September nearly all the seedlings and all the Green Mountain checks were completely killed, both leaves and stems. A few seedlings had stems and about one-fifth of the leaves remained free from blight infection, and a still smaller group had only a few infected leaves. There were no seedlings completely free from the disease. A number of the most resistant lines were found in a progeny of Katahdin, naturally fertilized. A few seedlings of the cross Chippewa × Katahdin, both of which are susceptible to blight, escaped with very little injury. From this test it was evident that there are different degrees of resistance; that resistant varieties can be obtained by inbreeding certain susceptible varieties and by crossing two susceptibles. The test showed also that lateness is not completely correlated with blight resistance or escape, since all the seedlings were comparatively late, but hundreds of them were killed by blight before they had time to mature.

Since 1932 a large number of varieties and seedlings have been tested for resistance, some of them at Presque Isle, Maine, and some in the greenhouse at Beltsville, Md., under conditions favoring heavy infection. At Presque Isle blight spores are sprayed on the plants under test on evenings preferably cool and damp. In the greenhouse steam is turned into the section in which the plants are being tested, to produce a high humidity, and the plants are then sprayed with spores of the fungus. Heavy epidemics are usually induced by these methods, and unless a variety is resistant, there is little chance of escape. A number of introductions from Germany and elsewhere, as well as a comparatively large number of progenies, have been put through these tests during the last 4 years. The results obtained with some of these were reported by Stevenson et al. (*67*) and need not be repeated here. It should be said, however, that there are now available hundreds of varieties and seedlings showing varying degrees of resistance to late blight. A few produced from seed received from K. O. Müller, Berlin-Dahlem, Germany, have completely escaped infection, even under epidemic conditions such as prevailed in the Presque Isle tests in 1936.

From the commercial standpoint one of the most promising selections up to the present time is from a cross of Chippewa × Katahdin. This variety came through the epidemic of 1932, unsprayed with bordeaux mixture throughout the growing season, with very slight injury. It has been included in the greenhouse tests at Beltsville and again in the field at Presque Isle in 1936 and produces a good crop, even when sprayed with blight spores. It has yielded slightly more than Green Mountain for an aveiage of 5 years at Presque Isle and has good cooking quality when grown at Aroostook Farm. Other promising seedlings highly resistant to blight are from a cross between No Blight and Katahdin. No Blight is described by Bonde (*6*) under the name Foster Rustproof, and Katahdin has been described by Clark et al. (*18*). No Blight is quite resistant to late blight. Katahdin is susceptible, but it carries a factor or factors for resistance in a heterozygous condition, as is shown by the fact that blight-resistant seedlings have been found in a progeny of Katahdin selfed. Some of the blight-resistant seedlings from the cross No Blight × Katahdin are being tested for yield and other characters. Two years' tests show them to be in about the same class as Green Mountain with respect to yield. Another cross from which a number of promising selections have been made had for parents Ekishirazu, a Japanese variety, and seedling 45349, the latter a seedling of Katahdin open-pollinated. Seedling 45349 was selected in 1932 and has shown a fair degree of resistance in a number of tests since that time.

Figure 5 shows the difference between the appearance of the vines of a resistant seedling on which very little late blight developed and the Green Mountain check, which was completely killed by the disease. Both of these were sprayed with blight spores to induce the epidemic.

The tubers of a number of the seedling varieties are resistant to tuber rot caused by the late blight fungus. Reiner Bonde, of the Maine Agricultural Experiment Station, has tested a number of them by putting blight spores on the surface of the tubers and then placing them in a moist chamber in a temperature conducive to development of rot. A number of the seedling varieties remained free from rot except where the skin was broken. The Green Mountain check rotted completely in a very short time (fig. 6). Many varieties therefore have been produced within the last few years by hybridization and selection that are resistant enough to late blight to be grown successfully without being sprayed even in years when this disease occurs in epidemic proportions. Several of these are promising also from the standpoint of other characters of commercial importance.

Resistance to Common Scab

Another disease that takes its toll wherever potatoes are produced is the common scab caused by *Actinomyces scabies*. Scab is not so noticeable in its effects on yields as is late blight, but it affects the market quality and hence the value of the tubers.

The behavior of a comparatively large number of varieties under widely different conditions indicates that resistance to scab occurs in the potato in varying degrees. Complete immunity has not as yet been demonstrated. Concerning this point, Berkner (*3*) says that absolute immunity does not appear to exist, but that there are decided

hereditary differences in the degrees of resistance and susceptibility.

The nature of resistance to scab has been studied by several investigators. The fact that the varieties that have shown the highest degrees of resistance possess a thick russet skin has led some to believe that resistance is dependent upon this type of skin. Histological studies of several varieties by Lutman (*37*) led him to conclude that thickness of skin determines the resistance of the tubers to scab and that color does not play an important role. Stuart (*70*) showed the fallacy of the prevailing conception that the russet type of skin is the basis of freedom from scab and pointed out that scab was abundant

Figure 5.—Two seedlings of a progeny segregating for resistance to late blight: No. 319 (left) practically free from late blight; no. 320 (center) completely killed by this disease. At right, susceptible Green Mountain check. August 21.

on the tubers of Cambridge Russet during a period of 6 years. In tests of a large number of seedlings, Darling, Leach, and Krantz (*21*) found a high degree of resistance in smooth and thin-skinned seedlings as well as in russet types. No correlation was shown to exist between color of tuber and scab resistance.

Some of the American commercial varieties, such as Russet Rural, Russet Burbank, and Mahr Russet, have been known for a number of years to be resistant to scab. A number of European varieties, Richter Jubel, Arnica, Hindenburg, Oststarke, Treff As, Rheingold, and Ostragis, are also resistant, as was reported by Schlumberger (*62*, *63*). These varieties, with the addition of a U. S. D. A. seedling, no. 44537, which is highly resistant to scab, have become the basis of breeding for resistance to this disease. At Presque Isle, Maine, a large

number of other varieties also have been tested for the purpose of obtaining additional material. The first tests, 1930–33, were conducted on land that was known to produce scabby potatoes in previous years. The results were somewhat variable. In 1934–36 lime was applied, before planting, at the rate of about 1 ton per acre, to land that was known to produce some scabby potatoes in previous seasons.

In the tests five hills of the variety or seedling to be tested were planted in alternate hills with Green Mountain, which is susceptible to scab. Comparisons were made between the seedling or variety and the Green Mountain check. The material included in these tests

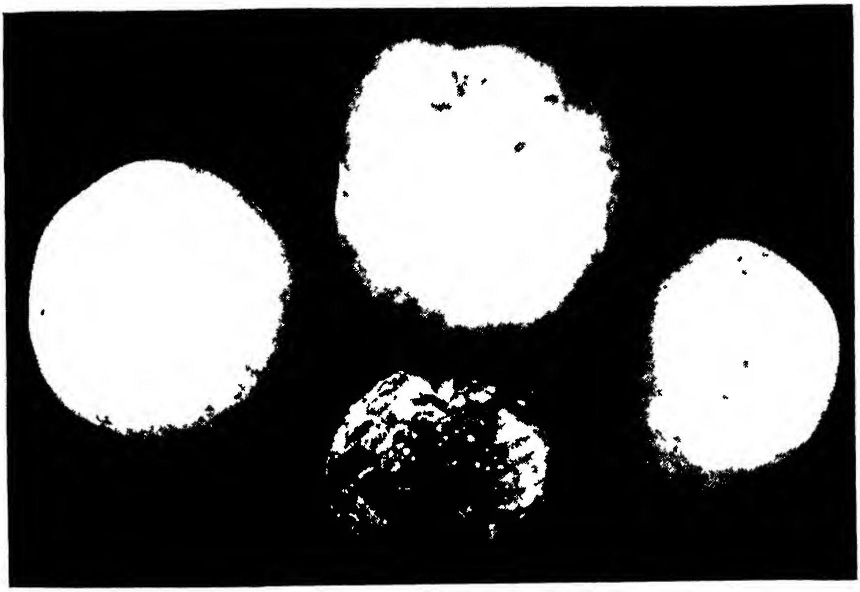

Figure 6.—Resistance of tubers to late blight. Sound tubers, seedling no. 336–302; decayed tuber, Green Mountain. Both lots artificially inoculated with spores of the organism that causes late blight.

consisted of varieties of North American, European, and Asiatic origin, a collection of South American varieties obtained by the MacMillan-Erlanson expedition, and a number of progenies resulting from selfing certain varieties, as well as progenies from crosses. Several of the European varieties, including Hindenburg, Richter Jubel, Ackersegen, Arnica, and Hindenburg × Centifolia No. 9, which had been introduced because of their resistance to this disease, proved to be highly resistant in the scab test plots. All of these produced less than 1 percent of the amount of scab found on the Green Mountain checks. None of them had enough scab lesions on the tubers to classify them as scabby potatoes, while the Green Mountain tubers could not have been sold for table stock.

Golden, a new variety recently produced by the Department, was found in the 1935 tests to have about one-fifth as much scab on the

tubers as was found on the Green Mountain checks. A few North American varieties—Russet Rural, Russet Burbank, and Mahr Russet—were intermediate in their resistance. A relatively large number of crosses have been made in an effort to determine the breeding behavior of some of these varieties. Although the data will not permit the formulation of an exact genetic hypothesis, a number of facts have been brought out in these tests. The progeny of a cross between two scab-susceptible varieties, Columbia Russet and Katahdin, were all susceptible. Another cross between two resistant varieties, Ostragis and Hindenburg, produced a progeny in which all were resistant to scab. Other crosses between resistant varieties showed segregation for resistance in the first generation

Figure 7.—**Resistance to common scab. The second and third tubers, seedling no. 416–50, are highly resistant to this disease. The first and fourth tubers are from the Green Mountain check grown in the hills adjacent to the seedling variety.**

A heavily russeted seedling variety, no. 44537, proved to be highly resistant to scab. This variety produces good pollen and is self-fertile. A progeny of the variety, selfed, segregated for resistance and russeting. A number of the russeted types and a few of the smooth white-skinned segregates were resistant to scab. This variety has been crossed with susceptible and resistant varieties. The progenies of certain combinations segregated for resistance and susceptibility. Figure 7 shows a resistant segregate in comparison with the Green Mountain check. One of the most promising progenies from the standpoint of both resistance and vigor resulted from a cross between Richter Jubel and seedling no. 44537. This progeny segregated for russet and smooth skin and for resistance and susceptibility to scab. A large number of both the russet and the smooth types were resistant to scab. A number of these were desirable from the standpoint of shape, depth of eye, color of tuber, and vigor, as well as scab resistance, and were selected for future work. It is too soon to predict their commercial possibilities, but some of them are the most promising scab-resistant seedling varieties produced so far.

Practical Results

The foregoing results show progress. A practical accomplishment has been the distribution within the last 5 years of six new varieties of potatoes. Others are on the way. Warba and Red Warba have been distributed by the University of Minnesota, and four varieties—Katahdin, Chippewa, Golden, and Houma—by the Department. Warba is an early variety, and from reports from different sections of the country it seems to be outstanding among the early varieties in yielding ability. Red Warba has not been tested thoroughly, but it is assumed to be similar to Warba in all its characters except color, since it originated from that variety as a vegetative mutation.

The four new varieties distributed by the Department in cooperation with the State experiment stations are all resistant to the virus disease mild mosaic, which causes so much running out of the Green Mountain variety in Maine. Chippewa is being increased as rapidly as the available supply of seed stock will permit. It is medium early, has high yielding ability, and is widely adapted. Golden is a yellow-fleshed variety, like most of the potato varieties used for food in Germany. There is a limited demand for this type in the United States, and Golden is being grown by 50 or 60 growers in Maine and by a few in the Upper Peninsula of Michigan. The variety is not widely adapted, but where it can be grown successfully it is prized because of its very high yields, good cooking quality, and scab resistance.

Houma was selected from a group of U. S. D. A. seedlings grown at Houma, La., by J. C. Miller, of the University of Louisiana, because of its high quality and adaptation to the Houma potato-growing section of that State. The season just past showed this variety to be somewhat drought resistant, but not sufficiently so to withstand the severe drought in the Middle West.

Katahdin (fig. 8) was the first variety to be introduced by the Department, and for that reason it is the most widely known of the Department introductions. It has had its ups and downs but is still on the increase. In a recent bulletin Moore and Wheeler (*40*) say in part:

> An outstanding characteristic of the Katahdin that should appeal to most Michigan growers is its ability to produce satisfactory yields of good type tubers even under heat and drought conditions. The Katahdin sets fewer tubers per hill than the Rurals and develops them earlier. This characteristic often enables it to surpass Rurals in yield of marketable potatoes, particularly when the season is unfavorable for the Rural varieties. The results of tests and the experiences of many growers confirm this statement.

Four seasons unfavorable for Rurals but in which Katahdins have been grown successfully have occurred in Michigan since 1930. This is no doubt responsible for the fact that most of the 500,000 bushels of Katahdins grown in Michigan in 1935 were kept for the 1936 planting, although it is not definitely known how the market will receive this variety. Preliminary tests have shown that the Katahdin as grown in Michigan is superior to the standard varieties in market quality and is equal at least to the Rurals in cooking quality. In the fall of 1935, 53 bushels of Katahdin were distributed in bushel lots to 53 hotels in Michigan, Ohio, Illinois, and Indiana.

138904°—37——28

Fourteen hotels had a few criticisms to make. Thirty-nine reported that they found the Katahdin an excellent potato for baking, boiling, and frying, and that they were well pleased with the color and texture of the cooked product. Many of the hotel chefs made favorable comments on the attractive appearance of the Katahdin and were

Figure 8.—A field of Katahdin. Note vigorous vine growth almost covering rows.

well pleased with its smooth, thin skin and shallow eyes, which reduced waste in peeling.

These same characteristics, smooth shape and shallow eyes (fig. 9), combined with the resistance to mild mosaic, induced the representative of Argentina, looking for seed potatoes in the United States and Canada, to recommend the purchase of a large quantity of seed stock of the Katahdin variety for that country. He is said to have purchased a quantity of Chippewa, too, although the price of these was comparatively very high. He refused to consider the deeper eyed types such as Irish Cobbler and Triumph.

The potato-breeding project as it now stands and the results up to the present time demonstrate clearly the necessity and the advantages of cooperation in scientific enterprises. The project is dependent on the Division of Plant Exploration and Introduction, Bureau of Plant Industry, United States Department of Agriculture, for new material carrying new genes for resistance and other important characters. Within recent years varieties resistant to late blight, others resistant to scab, and still others that are said to be resistant to leaf roll have been obtained. The plant breeders and horticulturists make the crosses and grow the progenies. The plant pathologists create the epidemics and secure the disease data. The Bureau of Home Economics of the Department, assisted by the horticulturists, makes the cooking tests. The State experiment stations cooperate in testing the new seedlings produced either by the Department or by

any other institutions to determine their range of adaptability. If any of the investigators find a seedling adapted to growing conditions in their State they take the responsibility of increasing the seed and seeing that it is distributed to growers. All these steps are necessary for the success of the breeding work, and all the organizations share the credit for its accomplishments.

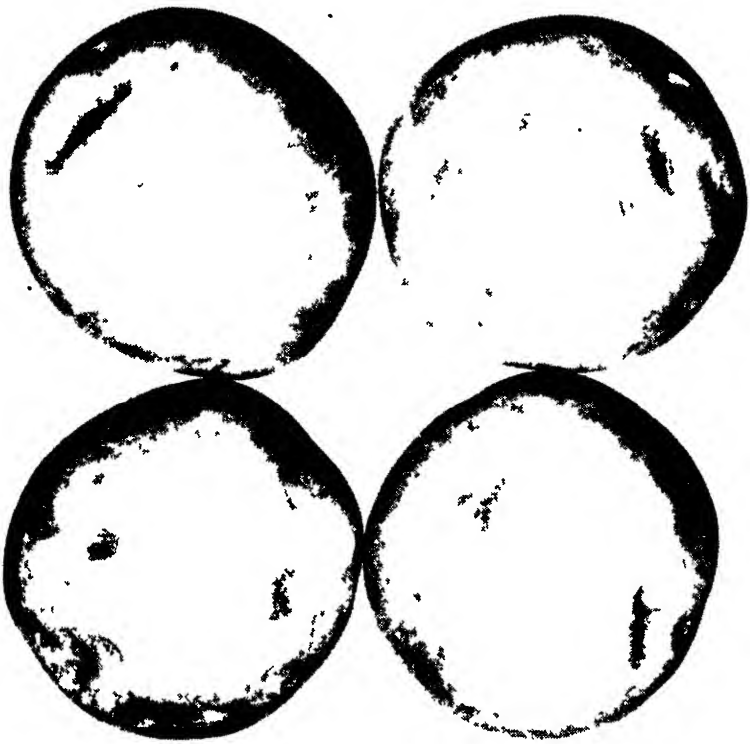

Figure 9.—Tubers of the Katahdin potato. The good shape of the tubers and the shallow eyes are outstanding features of this variety.

A summary of the results of breeding work up to the present time shows:

(1) A large number of varieties resistant to one virus disease, mild mosaic.

(2) One variety and several of its progenies immune to another virus disease, latent mosaic.

(3) Many varieties resistant to late blight, several showing commercial possibilities.

(4) A large number of varieties resistant to scab, too new to predict the possibilities.

(5) One variety as early as Irish Cobbler, but much smoother and with shallower eyes, being tested by farmers and about ready for naming.

(6) Six varieties named and distributed.

(7) The Katahdin and Chippewa firmly established as commercial varieties and entering into the South American seed trade because of their attractive appearance and disease resistance.

BREEDING METHODS, GENETICS, AND CYTOLOGY [2]

THE introduction of new varieties or species may not appear to be a plant-breeding procedure, yet it is fundamental to a well-rounded breeding program. It is improbable that varieties will be found in foreign countries adapted to any of the potato-growing regions of the United States, but even if the new introductions cannot compete with the standard varieties they may carry genes for certain characters that will make them extremely valuable from the breeding standpoint. For example, a number of varieties have been introduced recently from Europe that are resistant to late blight, others that are resistant to common scab, and still others that are reported to be resistant to leaf roll. These are being used in crosses for the purpose of combining the genes for resistance with those for other characters of economic importance. In the last 30 years approximately 10,000 sorts, including commercial varieties, seedling varieties, and species, have been collected by the Department. Thousands of these have been discarded because they were considered of no value, but others have provided a wealth of material for the work of potato breeders.

ADVANTAGES AND LIMITATIONS OF THE METHODS USED

Selection is the principal tool of the plant breeder regardless of the method employed. Selection of clons or strains from a variety has often been designated as a special method. This method is limited in its application, since its success depends on the value of the bud sports or mutations that occur in a variety or clonal line.

Varietal crossing has been universally employed by potato breeders. As a rule, varieties are heterozygous or mixed in their inheritance for most characters and they will segregate into different lines when they are self-pollinated. Because of pollen sterility not all varieties can be selfed, and the only way to use valuable genes in a self-sterile variety is to make it a female parent in crosses. If both parents are heterozygous for the characters under consideration, segregation will take place in the first generation. Not all possible recombinations of characters can be expected in the first generation, however, since one of the parents may be homozygous or pure for some dominant character, in which case all the plants of the first generation would resemble that parent in that particular character. As an example, in some instances the first generation of a late variety crossed with an early may be all late, no segregation into late and early lines appearing. There are certain advantages in using crosses between heterozygous material, and also certain disadvantages. One advantage is that segregation occurs in the first generation; and if, because of sterility, a second generation cannot be produced, it may be possible in many instances to obtain the desired recombination in the first generation. Another advantage is that combinations differing widely in vigor often occur when heterozygous parents are used, and individuals are often found more vigorous than either parent. The main disadvantage in the use of heterozygous lines as parents is the difficulty of obtaining exact genetic knowledge of the breeding material.

---

[2] This section is written primarily for students or others professionally interested in breeding or genetics.

Sib mating, or sister-brother mating, is one system of inbreeding and is useful for several purposes. It helps to determine the degree of homozygosity or uniformity of inheritance of a particular line. Selfing each of the sibs would of course give the same information, but this cannot always be accomplished because of the self-sterility of many lines. In some cases, too, segregates from a cross between two sibs are more vigorous than either parent.

Backcrossing is employed to good advantage in potato breeding, but as most of the parent material is heterozygous, it is not so efficient as if homozygous lines were available. If the original parents are homozygous all the plants of the first generations have the same inheritance although they differ in appearance, and a backcross to any one of them gives essentially the same results as it would to any other. If parents heterozygous for certain characters are used, the first-generation hybrids may differ genetically among themselves, and therefore would give different results in backcrosses. More work must be done to accomplish the same results when heterozygous parents are used than would be necessary if vigorous fertile homozygous parents were available. But in any case backcrossing is a useful method, and it is employed very frequently to obtain certain combinations of characters.

Selfing is employed at least to some extent by all plant breeders. Selfing and the recombining of selfed lines is being used extensively by corn breeders, but potato breeders have depended to a large extent on other methods to obtain desirable recombinations. The self-sterility of many clonal lines and the loss of vigor brought about by intensive selfing are probably two of the reasons why potato breeders have not generally adopted this method. Another reason is that the potato as grown commercially is propagated from tubers, and the grower gets a comparatively uniform crop even if the variety is heterozygous for certain characters. This is not true with crops propagated from seed, as these must be genetically uniform in order that a uniform crop may be produced. For genetic studies it likewise is desirable to obtain homozygous potato lines that are fertile. From the commercial standpoint some of the most promising material is obtained by selfing one or two generations, selecting the best of these selfed lines and outcrossing to one of the best commercial varieties. This method has sometimes been referred to as top crossing.

Strain building is not a method in itself but is a system of breeding that makes use of all methods. The system can best be described by an example from the disease-resistance work now in progress at Presque Isle, Maine. A few blight-resistant varieties were obtained from foreign countries, and several seedling varieties produced by the Department were selected that were only slightly injured by the blight epidemic of 1932 in the breeding plots at Presque Isle. The most promising of these from the standpoint of blight resistance were crossed with varieties carrying genes for high yield, good shape, shallow eyes, resistance to mild mosaic, and other characters of economic importance. The progenies were tested for blight resistance, and the most promising seedlings were selected. Some of these were selfed, some of them sib-mated, some backcrossed to the resistant parent, and others outcrossed to unrelated blight-resistant varieties. The

resulting progenies were again tested for blight reaction and selections made, taking into consideration resistance to blight, shape and color of tuber, depth of eye, and vigor. By such a combination of the methods of introduction, varietal crossing, sib mating, backcrossing, and selfing, it should be possible to get any desired recombination of the genes of the parent cultures. Some of the resulting new varieties thus produced should be as good as or better than the commercial varieties in yield, shape of tuber, etc., and superior to them in disease resistance.

The use of species hybrids is usually the last resort of the breeder interested in the production of superior horticultural varieties. It is true that in order to do the best work he must be acquainted with the wild relatives of the plant with which he is working, the characters they possess, and their behavior in crosses. Research with species and species hybrids, then, must be one aspect of any breeding project. It sometimes happens that a desirable character is not to be found in the cultivated varieties of a crop but is present in a related species, so that the desired combination of genes can only be obtained by making a cross between species. An illustration of this is found in breeding potatoes for resistance to late blight. At present, although a number of cultivated varieties are resistant to this disease, none has been found immune to its attacks. Some of the related species, however, do show immunity. Attempts have been made from time to time to combine this immunity with characters of commercial importance by the use of species hybrids.

By the use of all the available methods, if it were not for sterility, the number of new varieties that could be produced through recombinations would be limited only by the characters of the available parents and the number of offspring it is possible to grow.

Sterility a Major Handicap

Sterility, or lack of fruitfulness, which is very generally present in potato varieties, is the source of the greatest difficulty in sexual breeding, and in spite of much study of the condition it remains the greatest handicap of the potato breeder.

Salaman (*51*, *52*) and Heribert-Nilsson (*24*) found sterility of the anthers to be dominant to fertility. At first Salaman believed sterility was due to a single gene, but later Salaman and Lesley (*59*) indicated a more complex manner of inheritance. Edzell Blue, a variety that produces viable pollen, was heterozygous on its female side for male sterility. Krantz (*32*) points out that two commercial varieties, Green Mountain and Early Ohio, have produced fertile seedlings in progeny grown from self-fertilized seed. The Green Mountain variety usually sets some seed under favorable growing conditions. The Early Ohio variety sets no seed. It apparently produces viable pollen under very favorable circumstances.

Kessler (*27*) described a number of morphological characters of the pollen of various varieties and their relation to its germinating power. Neither the shape in itself nor the amount of granulation was an indication of sterility. A much surer test was obtained by staining with carmine in hydrochloric acid. The sterile pollen remained unstained. The influence of culture media, air, humidity, temperature, and light was considered. Light had an adverse effect, as had also temperatures

above 95° and below 46° F. Studies of pollen tube development after artificial pollination indicate that the pollen tube of a particular variety may reach the ovule successfully when applied to certain varieties but not when applied to others.

Clark (*14*) enumerates four different types of plant sterility—premature abscission or dropping of buds and flowers, lack of viable pollen, hybridity, and physiological incompatability between parents.

Premature abscission constitutes a very effective type of sterility, since it is obvious that fruit cannot be produced when buds fall before opening or flowers persist for only a few hours. If this is not very pronounced, so that a few flowers open and persist for a few days, they may, under favorable climatic conditions, produce fruit when pollinated with viable pollen. The anthers of such flowers produce little pollen, and this is rarely, if ever, viable.

Pollen sterility is very strongly manifested in the cultivated varieties of potatoes. This condition appears to be inherent in the species. Stout and Clark (*68*) studied the pollen of 170 commercial varieties and 513 seedling varieties, representing material from many parts of the world. They failed to find a single variety in which there was not a fairly large percentage of sterile pollen. Of seven wild species studied, only one, *Solanum commersonii* Dun., showed the presence of this type of sterility to any marked degree.

Salaman (*51*) demonstrated the hereditary nature of sterility in potato a number of years ago. He stated that the potato plant, which is normally bisexual, carries a dominant factor that inhibits pollen formation at the pollen mother cell stage or even earlier. In a later paper Salaman and Lesley (*59*) showed by reciprocal crosses that the greater portion, if not all, of the sterility is inherited through the female parent. The fact that the eggs are often viable under conditions lethal to the pollen is well known and makes possible the use of many varieties as seed parents that cannot be used as pollen parents.

Irregular chromosome behavior has been advanced by a number of investigators as one of the chief causes for hereditary sterility. Longley and Clark (*36*) presented a study of chromosome number and of meiotic behavior in tuber-bearing forms of *Solanum*. In 37 cultivated varieties grown in the United States there was found a somatic chromosome number of 48. The meiotic behavior of this group varied from regular in a few cases to extremely irregular in many of the varieties. Only the few varieties with a regular chromosome behavior produced an appreciable amount of viable pollen; varieties with an irregular chromosome behavior produced practically no pollen.

Genetic factors and chromosome behavior no doubt make the development of sterility possible, since varieties are inherently different in the degree to which they will bloom or set seed. But seed setting is also influenced by environmental factors to a marked degree. Some varieties will set seed under a wide range of conditions, while others have never been known to set seed even under favorable conditions. Stow (*69*) showed that environmental conditions even influenced the chromosome behavior. He stated that—

> the abnormal division is neither connected with the hybrid nature of the plant nor the nutritive correlation within its body; but is rather due to the environmental conditions or certain special nature of the plant itself.

He considered that sterility was mainly the result of abnormal pollen mother cells, which he observed with exposure to high temperatures (25°–35° C.). "At lower temperatures (15°–20° C.), on the other hand, the reduction proceeded in a regular manner, producing normal pollen grains."

That length of day has an influence on flowering and seed setting has been shown by Stevenson and Clark (*66*). In the experiment reported by them that was conducted in the greenhouse at the Arlington Experiment Farm, Arlington, Va., the application of artificial light for 5 hours to 20 potato varieties to supplement the daylight period stimulated vine growth and blossoming to a remarkable degree. The varieties used in this experiment were grown also in the field at Presque Isle, Maine, where 10 of them produced seed in varying degrees of abundance, while the remaining 10 produced no seed. In the greenhouse experiment at Arlington, 70 percent of the plants in the 10 more responsive varieties came to full bloom under the lights, while only 5 percent of the checks without lights bloomed. In the less responsive varieties only 20 percent of the plants under the lights bloomed, and no blossoms were produced by the check. No naturally fertilized seed was produced, but inbred seed was readily obtained under the lights by hand-pollinating self-fertile plants. The chromosome behavior of the plants grown under the light was much more regular than that of the same varieties grown without lights.

The effect of environment on blooming was shown by Stout and Clark (*68*). Halved tubers of 15 varieties were grown, one set at Presque Isle, and the corresponding halves at the New York Botanical Garden. All the varieties bloomed profusely at Presque Isle. In New York only 2 of these varieties bloomed well, 3 produced a few flowers, and 10 produced no flowers that opened. Conditions are favorable for seed setting nearly every season at Presque Isle. A few other places in the United States have been found favorable for seed production in potatoes. At Estes Park, Colo., which has an elevation of 7,500 feet, seed sets in most years quite readily. Another striking example of the effect of environment is found in the potato-breeding work in Minnesota. Seed cannot be produced on a large number of varieties and strains at University Farm, St. Paul, but many of the same varieties will produce seed at Duluth on Lake Superior, and even better at Castle Danger on the north shore of the lake.

Complete or partial sterility may result from hybridizing, though there seems to be no general rule regarding the behavior of hybrids with respect to sterility, as some combinations produce hybrids with a very high degree of fertility, while the progeny resulting from other crosses may be completely sterile. In a species cross between *Solanum fendleri* A. Gray and *S. chacoense* Bitt., produced by Clark (*15*), the first generation was completely sterile when selfed and when backcrossed with either parent. Bukasov (*10*) reports that hybrids of *S. acaule* Bitt. with *S. andigenum* and with *S. tuberosum* are sterile.

In some species of plants certain combinations of crosses within the species as well as selfed pollinations fail to produce seed even though there is no degeneracy in either pollen or egg cells. Other combinations in the same species may produce an abundance of fruit. This type of sterility has been referred to as physiological incompatibility.

It was not found to occur in the cultivated varieties of potatoes studied by Stout and Clark (*68*), but was reported by Clark (*14*) to be present in the wild species *Solanum caldasii glabrescens* Dun. and *S. chacoense*.

Genetics of the Potato

Definite genetic data are available for only a comparatively few characters of the potato. Such data are accumulating from year to year, however, and as the knowledge grows the solution of many breeding problems becomes less complex. A partial summary of potato characters, their genetic behavior, the name of the investigator making the report, and the literature citations are given in the appendix.

A study of the table shows the usual array of gene interactions—dominance and recessiveness, complementary genes (either 2 or 3), multiple genes, cumulative effects, and inhibiting genes.

In several instances a number of different ratios are reported for what is apparently the same character; but it must be remembered that characters that look alike may be genetically different and as a result will behave differently in inheritance.

From the material available it is seen that little is known concerning the genetic behavior of some of the most important characters of the potato, such as yield, cooking quality, and resistance to various diseases, but the breeding work is being centered around such characters at present, and it is believed that, while they may be rather complex in their genetic behavior, they will all follow the general rule that a genetic character is the end result of the interaction of genes and environment.

Potato Species, Their Chromosome Numbers, and Some of Their Valuable Characters

While it is necessary for the breeder to obtain a thorough knowledge of the cultivated varieties and their important economic characters, it is also important to know the related wild forms and species of potatoes. It is true that new genes and gene combinations are being brought to light in the cultivated varieties, but it is quite improbable that all the problems can be solved by the recombinations of genes available in this group.

Much work has already been done with the species of *Solanum* related to the potato, and a fund of valuable information is available concerning them. The species fall into five groups with respect to $2n$ chromosome numbers, those having 24, 36, 48, 60, and 72 in vegetative tissues, as reported by several investigators. According to Bukasov (*9*), cultivated varieties have been found in the first four groups. Crosses between species with different chromosome numbers are as a rule difficult to obtain. For example, crosses between species of the 24 group and the 48 group are very rare, although many attempts have been made to produce them. Certain species crosses have been reported, however, and as knowledge increases concerning the causes of incompatibility and sterility, it may be possible in the future to get hybrid combinations that at present seem quite impossible. A partial list of species of the *Tuberarium* section of *Solanum*, with their $2n$ chromosome numbers, is given in the appendix.

Characters that would be especially valuable if they could be combined with those of the best commercial varieties have been found in a number of species. Among these are resistance to drought, frost, potato wart, viruses, and late blight. The characters for short-day development and short rest period are found in some of the species also. The character for short-day development might be valuable in potato districts where the crop is grown during the winter months under conditions of short-day length. A list of the species known to possess valuable characters from the breeding standpoint is also given in the appendix.

APPENDIX

Early breeders of potatoes and the varieties originated by them

Breeders	*Varieties*
O H Alexander, Charlotte, Vt	Charles Downing, Dakota Red, Everett, Garfield, Green Mountain, Reliance, Trophy, White Mountain
Martin Bovee, Northville, Mich	Bovee, Early Michigan, Pingree
Albert Bresee, Hubbardton, Vt	Early Rose, King of the Earlies, Peerless, Prolific
C W Brownell, Essex, Vt	Beauty, Best, Centennial, Early Telephone, Eureka, Superior, Winner, Vermont Beauty
Luther Burbank, Lancaster, Mass	Burbank (Burbank's seedling)
E S Carman	Carman No 1, Carman No 3, Rural New Yorker No 2, Sir Walter Raleigh
E L Coy, Hebron, N Y	Early Beauty of Hebron, Late Beauty of Hebron, Early Puritan, Empire State, Late Rose, Noroton Beauty, Thorburn, Vaughan, White Elephant
Thomas Craine, Fort Atkinson, Wis	June Eating, Keeper, Potentate
C E Goodrich, Utica, N Y	Calico, Cuzco, Early Goodrich, Garnet Chili, and several others which were short lived in the commercial trade
D W Heffron, Utica, N Y	Chicago Market, Climax
C G Pringle, Charlotte, Vt	Alpha, Adirondack, Rubicund, Ruby, Snowflake
Arthur Rand, Shelburne, Vt	Champion, Delaware, Matchless, Improved Peachblow, Silver Skin
Alfred Reese	Early Ohio
G T Safford, North Bennington, Vt	Gold Coin
F B Van Ornam, Lewis, Iowa	Extra Early (Burpee's), Great Divide

TABLE 1 —*Potato varieties available in the United States known to have characters of value to breeders*

Variety	Source	Superior characters
Katahdin	Department of Agriculture	Fertility, resistance to mild mosaic good shape high yield
Chippewa	do	Resistance to mild mosaic, good shape, high yield, early tuber development
Golden	do	High yield, some resistance to scab
Houma	do	High yield, some drought resistance good shape good cooking quality
24642	do	Fertility, resistance to mild mosaic some earliness
41956	do	Immunity to latent mosaic and resistance to mild mosaic
44488	do	Resistance to late blight high yield
44537	do	Fertility, resistance to scab
45075	do	Fertility earliness good shape
45208	do	High yield, good cooking quality
45349	do	Resistance to late blight
46110	do	High yield
46125	do	High yield and cooking quality
46422	do	Fertility, yield
46923	do	Fertility and earliness
182 7	do	Fertility and resistance to late blight
336-7	do	Do
336-18	do	Do
336-123	do	High yield and resistance to late blight
336-144	do	Fertility and resistance to late blight
336-302	do	Resistance to late blight
3868-8	Department of Agriculture from German seed	Do
3897-90	do	Do

Table 1.—*Potato varieties available in the United States known to have characters of value to breeders*—Continued

Variety	Source	Superior characters
444-12	Department of Agriculture.	Fertility and resistance to scab.
Green Mountain	United States	High yield, quality.
Rural New Yorker No. 2	do	Good tuber type, hardiness.
Russet Rural	do	Do.
Russet Burbank	do	Good quality, resistance to scab.
Charles Downing	do	Good quality and tuber type.
Irish Cobbler	do	Earliness and wide adaptability.
Triumph	do	Earliness.
Early Rose	do	Do.
Early Ohio	do	Do.
Mahr Russet	do	Resistance to scab.
Warba	Minnesota	Earliness, yield.
Red Warba	do	Do.
Arnica	Germany	Resistance to scab.
Hindenburg	do	Do.
Richter Jubel	do	Fertility, resistance to scab.
Ostragis	do	Resistance to scab.
Rheingold	do	Do.
Ackersegen	do	Resistance to late blight.
Ekishirazu	Japan	Do.
No Blight	Canada	Do.
Paisley's No. 1	do	Do.
Paisley's No. 2	do	Do.
Paisley's No. 3	do	Do.
Paisley's No. 4	do	Do.
Imperia	do	Resistance to leaf roll.
Triumf	Netherlands	Do.
Albion	do	Do.
Friso	do	Do
West Brabander	do	Do.
Bevelander	do	Do.
Noordeling	do	Do.
130.5-24	North Carolina	High yield.
101-91	Michigan	Good tuber shape, high yield on muck.
155-29	do	Do.
155-49	do	Do.
401-23	do	Do.
472-10	do	Do.
472-33	do	Do.
472-53	do	Do
N. D. No. 64	North Dakota	High yield, good shape.
N. D. No. 82	do	Earliness, good shape.
N. D. No. 86	do	Earliness, high yield, and good shape.
N. D. No. 87	do	Russet.
F. B. 32-1	Colorado (Fort Collins).	High yield, good shape.
L. 32-1	do	Russet.
E. 32-7	do	Earliness, high yield, good shape.
E. 32-8	do	High yield, good shape.
252	do	Fertility, shallowness of eye.
C. S. 48	Colorado (Greeley)	Fertility.
C. S. 50	do	Do.
C. S. 98	do	Do.
C. S. 106	do	Resistance to fusarium.
C. S. 125	do	Do.
C. S. 133	do	Do.
C. S. 155	do	Do.

Table 2.—*Potato lines and progenies known to have superior genetic characters, produced by the U. S. Department of Agriculture and by the New York (Cornell) and Minnesota Agricultural Experiment Stations*

UNITED STATES DEPARTMENT OF AGRICULTURE

Cross no.	Parentage	Superior characters
774	S 41956 × Katahdin	Resistance to latent and mild mosaics.
792	S 41956 × S 45075	Resistance to latent mosaic.
926	Katahdin × S 45075	Earliness, resistance to mild mosaic.
1028	Katahdin selfed	Resistance to mild mosaic.
295	Russet Rural × S 44537	Resistance to common scab.
528	Richter Jubel × S 44537	Do.
336	No Blight × Katahdin	Resistance to late blight and mild mosaic.
618	S 45349 × Ekishirazu	Resistance to late blight.
690	S 45349 × Katahdin	Do.

TABLE 3.—*Potato characters, their genetic behavior, and the investigators and reference numbers*

Character	Genes and interactions	Segregations	Investigators and reference numbers
Flower color:			
Purple × white	Purple dominant to white		East (*22*).
Lilac × white	Lilac dominant to white		Fruwirth (*23*).
Blue violet × white	Blue violet dominant to white.	3 blue violet : 1 white	Müller (*41*).
Light blue (selfed)	Heterozygous	Monogenic	Heribert-Nilsson (*24*).
Light blue × white		1 colored : 1 white	Do.
Violet blue (selfed)	Multiple factors	Violet-blue, red, reddish purple, dark and light blue and white.	Do.
Red × white	2 complementary genes $D+R$ for red.		Salaman (*53*).
Purple × white	3 complementary genes $D+R+P$ for purple.		Do.
White × white		In some strains colored and white.	(Salaman) Matsuura (*39*).
White (selfed)		do	Do.
Light lilac (selfed)	Complementary	9 colored : 7 white	Clark and Stevenson (*18*).

Table 3.—*Potato characters, their genetic behavior, and the investigators and reference numbers*—Continued

Character	Genes and interactions	Segregations	Investigators and reference numbers
Tuber color:			
White (selfed)	Homozygous	All white	Salaman (*52*, *53*).
Red (selfed)	2 complementary genes $R+D$ for red.	9 red : 7 white	Do.
Dark purple × white.	3 complementary genes $R+D+P$ for purple.	13 purple : 12 red : 4 white (F_1).	Do.
Dark purple (F_1) selfed.		73 purple : 24 red : 75 white (F_2).	Do.
Light red × yellow	Heterozygous	1 red : 1 yellow (F_1), various grades of red, many having blue or dark-blue striping, also plants with colored eyes.	Heribert-Nilsson (*24*).
Yellow × yellow		Yellow and 10 percent blue black, blue, red or pale red.	Do.
White (*S. edinense* selfed).	*G* and *H* complementary, *Y* inhibitor.	13 colored : 40 white	Muller (*41*).
White (*S. edinense*) × white (*S. tuberosum*).	do	21 colored : 40 white	Do.
Parti-colored	3 genes complementary; *B*, basic, *D*, diluting, $M+D$= parti-colored pattern.		Kelly (*26*).
Do	Multiple allelomorphic series for uniformly colored parti-colored and white.		Collins (*20*).
Red skin color	3 genes complementary, $D+R$=parti-colored, $D+R+A$=uniformly colored.		Krantz (*33*, *34*).
Red cortical color	3 genes complementary, similar interaction as for skin color.		Do.
Red color	Genes complementary, $A+D$=parti-colored, $A+D+R$=uniformly colored; linkage between *A* and *R*.		Asseyeva (*1*).
Do	Genes complementary, $R+S+D$=red skin color, $R+S$=red eye color.	27 colored : 37 white, 9 red-eyed : 7 white-eyed.	Sirks (*64*).
Color	Genes complementary, $D+R$=red, $D+R+P$= purple, and *H* an incompletely dominant inhibitor.		Black (*4*).
Red (selfed)	2 genes complementary	9 colored: 7 white	Huber (*25*).
Purple (selfed)	Single gene, color dominant.	1 dark purple: 2 light purple: 1 white.	Krantz (*31*).
Colored (selfed)	Complementary, $C+I$= colored.		Müller (*41*).
Colored × white	$C+I$+inhibitor Z=white	All white	Do.
Tuber flesh color:			
Flesh color	Multiple genes		Black (*4*).
Do	2 genes, 1 giving yellow in plant homozygous or heterozygous, other homozygous only.		Huber (*25*).
Stem color:			
Red *v.* green	Single gene, red dominant		East (*22*).
Medium red (selfed)		1 dark: 2 medium: 1 light	Salaman (*52*).
Pigment	3 genes complementary, a fourth gene an inhibitor.		Müller (*41*).
Colored internodes	3 genes for color	36 blue:9 red:19 white for young internodes; 12 blue: 3 red: 1 white for old internodes.	Sirks (*64*).
Seedling and sprout color:			
Seedling color	3 genes complementary	Seedling color associated with flower, stem, and flesh colors.	Müller (*41*).
Seedling color (blue, red, green).	2 or 3 genes complementary.		Sirks (*64*).
Sprouts, blue purple *v.* red purple.	Single gene blue-purple dominant, same as *P* for tuber color.		Asseyeva (*1*).

TABLE 3.—*Potato characters, their genetic behavior, and the investigators and reference numbers*—Continued

Character	Genes and interactions	Segregations	Investigators and reference numbers
Habit of growth:			
Upright *v.* prostrate	At least 3 genes (multiple)	3 upright: 1 prostrate. 15 upright: 1 prostrate. 63 upright: 1 prostrate.	Salaman and Lesley (*58*).
Tuber shape:			
Round (selfed)		All round [1]	Salaman (*52*).
Oval (medium long) (selfed).		Long: oval: round [1]	Do.
Long (selfed)		All long [1]	Do.
Medium round (selfed).		Range from round to long	Clark and Stevenson (*18*).
Round (selfed)		Not all round	Heribert-Nilsson (*24*).
Tuber shape	Dependent on more than 1 gene.		Black (*4*).
Do	Three genes (multiple)		Huber (*25*).
Do	At least 4 genes (multiple)		Bartosh (*2*).
Depth of eye:			
Deep (selfed)	Deep incompletely dominant to shallow.	All deep eyed	Salaman (*52, 53, 54*).
Medium deep (selfed).		Deep, medium, shallow	Do.
Shallow (selfed)		All shallow	Do.
Deep *v.* shallow	Shallow eye dominant		East (*22*).
Time of maturity:			
Late × late		Wide range of variability in F_2.	Krantz (*31*).
Time of maturity	Multiple genes		Krantz and Hutchins (*35*). Müller (*42*).
Inheritance of cropping:			
Heavy *v.* light	2 or more genes, heavy dominant.		Salaman (*56*).
Immunity and resistance to potato wart:			
Immune (selfed)	Homozygous	All immune	Salaman and Lesley (*60*).
Do	Single gene immune dominant.	3 immune: 1 susceptible	Do.
Do	2 genes duplicate	15 immune: 1 susceptible	Do.
Do	2 genes complementary	9 immune: 7 susceptible	Do.
Susceptible × slightly resistant.		F_1, 29 percent resistant	Heribert-Nilsson (*24*)
Susceptibility *v.* resistance.	Susceptibility dominant		Collins (*19*).
Do	Resistance dominant		Orton and Weiss (*45*).
Do	3 genes (multiple) with varying values and cumulative.		Black (*5*).
Resistance to late blight:			
Resistance *v.* susceptibility.	At least 2 genes acting independently.	Six types of segregation; no close linkage with commercial characters.	Müller (*43*).

[1] Similar results were obtained by East (*22*), Fruwirth (*23*), and Krantz (*31*).

STRAWBERRY IMPROVEMENT[1]

GEORGE M. DARROW, Senior Pomologist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

THE strawberry came from North America, and some people think it is delicious enough to be a fair exchange for many of the fruits America has received from other parts of the world. Much of the work of developing the cultivated varieties has also been done in the United States; but so universal is the appeal of the strawberry that it is receiving the devoted attention of plant breeders in such remote lands as England, the Union of Soviet Socialist Republics (*47*)[2], and Japan (*33*, *34*, *35*, *36*).

The cultivated strawberry is definitely a product of plant breeding and is relatively young. The commercial development of this fruit has come principally since the Civil War, and most strawberry varieties now grown have originated within the past 45 years. Seventy years ago the strawberry was produced almost entirely near a few of the large cities. Now it is produced commercially in every State in the United States, as well as in the interior of Alaska. The introduction of improved varieties has been responsible for the steadily widening commercial production. When the first productive firm-fruited variety, Wilson, was introduced about 75 years ago, it became possible to grow the strawberry as far south as Florida and Louisiana. The hardy Dunlap, introduced about 35 years ago, made it reasonably safe to grow strawberries in northern Michigan, northern Maine, and parts of Canada. Later the origination of suitable high-quality varieties in Alaska made it possible to raise strawberries commercially even in that northern region. During the past century hundreds of thousands of seedlings have been tested, over 2,000 have been named, and a few score are widely grown; but these few score varieties combine the many qualities necessary for modern commercial production in every part of the United States and in every foreign country having a temperate climate.

The world-wide distribution of the strawberry may be attributed to three things: (1) The origination of firm varieties like the Wilson, adapted to widely different conditions; (2) the ability of the strawberry to grow from sea level up to elevations as high as 12,000 feet, in humid and dry regions, in the greenhouses of northern Europe,

---

[1] This report has been made possible by the cooperation of George F. Waldo, of the U. S. Department of Agriculture, at Corvallis, Oreg., and reports for their stations by J. H. Clark, of New Jersey; G. W. Gasser, of Alaska; A. N. Wilcox, of Minnesota; George L. Slate, of New York; S. M. Zeller, of Oregon; and H. E. Thomas, [illegible] W. S. R[illegible] Norway; [illegible] in the preparation of this report.

[2] Italic numbers in parentheses refer to Literature Cited, p. 482.

where the winter day is only 6 or 7 hours long, in Florida and southern California, where the winter day is 9 or 10 hours long, and in central Alaska, where the summer day may be 24 hours long (*17*); and (3) the high dessert quality and usefulness of the fruit, which matures in early summer when few fruits are available.

THE STRAWBERRY IS A TRAVELER

THE STRAWBERRY was born in North America, traveled to Europe, and finally returned home. But the strawberry that returned was very different from the one that went to Europe.

The cultivated strawberry of today is derived from two American species—the wild meadow strawberry (*Fragaria virginiana* Duch.) of eastern North America (figs. 1 and 2), and the beach strawberry (*F. chiloensis* (L.) Duch.), found along the Pacific coast from Alaska to California and along the coast of Chile (figs. 3 and 4). The beach strawberry is also found on the mountains of the Hawaiian Islands. The meadow strawberry has thin leaves and bright-red aromatic berries with deep-set seeds, and it grows freely in many soils and many

THE *work of the Department of Agriculture in strawberry breeding gives an excellent idea of the amount of detail involved in the production of improved varieties of plants. In Maryland, the Department has fruited 86,000 strawberry seedlings, representing artificial crosses among 150 different varieties. Of these, 1,999 were selected for further testing, and only 7 have been finally considered worth naming and introducing. In North Carolina, 54,000 seedlings have been grown and 1,245 selections have been made for further testing. In Oregon, the number of seedlings grown was 97,000 and the number selected for further testing is 1,331. In these few projects, then, more than a quarter of a million seedlings were involved; fewer than two out of a hundred were found to be worth further testing; and perhaps a score or fewer of new varieties will finally result. But of the few varieties already introduced, one is Blakemore, now considered to be the best preserving strawberry in the United States; another is Redheart, now more extensively grown than any other canning variety; and two others are Dorsett and Fairfax, which are superior in dessert quality to other varieties previously grown. In addition to this breeding work, 30,000 wild Rocky Mountain strawberries were collected in 1936 to be grown at Cheyenne, Wyo., with the idea of incorporating their superior resistance to cold, dry winters into cultivated varieties.*

locations. In contrast, the beach strawberry has thick leaves and dull-red berries with less aroma, and the seeds are usually raised above the surface. It is native only along the beaches. But hybrids are more vigorous and have wide adaptation.

First Improvement Was Made by American Natives

Before Columbus landed at San Salvador, unknown Indians of Chile, South America, had selected, from among the wild strawberries that grew only along the beaches, plants that bore fruit of exceptional size,

Figure 1.—The meadow strawberry of the eastern United States, *Fragaria virginiana.* The aroma, the beautiful color, and the wide adaptation of cultivated varieties come largely from this species.

"commonly as large as a walnut and sometimes the size of a hen's egg" (*48*). The fruit was pale red, with firm, meaty, almost white flesh and a delicate aroma (figs 3 and 4) More important, however, the selected plants, or at least one of them, had perfect flowers, while all the true wild beach strawberries and most of the wild meadow strawberries of North America have the sexes borne on separate plants (*61*). Just where the Indians found such a perfect-flowered wild plant, or how it came into cultivation, we do not know. An extensive search by the writer and others on the beaches of California, Oregon, and Washington has failed to locate a single perfect-flowered plant. One of the present needs in strawberry breeding is a survey of the coast of Chile, and particularly of Robinson Crusoe's island, Juan Fernandez, to locate plants having perfect flowers and to determine the value of the Chilean wild berries in breeding.

This early Chilean variety was taken to Peru in 1557, and it is still grown in Chile, Peru, Ecuador, and other South American countries.

The second important character in the story of the modern strawberry was a French officer, M. Frezier, who returned to Europe from Chile in 1714. He arrived at Marseilles, after a 6-month voyage, with five live plants of the Chilean variety (*48*). Plants of the meadow strawberry of eastern North America had already been taken to Europe, and from crosses of these two forms the modern strawberry was developed in Europe.

A third great character in the story was also a Frenchman, named Duchesne. In 1760, when only 19 years of age, he published a book of over 400 pages on the strawberry (*22*). He described the wild species, noted that some varieties had both pistils and stamens in their flowers and bore fruit, that others had only pistils and bore no fruit unless they grew near varieties that had stamens, and that still others had stamens and pistils but were sterile. Duchesne was probably the first to make actual crosses of strawberries.

Figure 2.—A pistillate-flowered seedling of a cross of the meadow strawberry (*Fragaria virginiana*) × Dunlap. Note the deep-set seeds.

A fourth character was an Englishman, Thomas Andrew Knight, who originated the Downton and later, about 1820, the Elton Pine, which is still grown in Europe (*29*). He made many crosses and proved that systematic breeding would result in improved varieties. He was really the world's first systematic fruit breeder. Best of all, he was a scientist who combined his scientific studies with practical breeding to secure better varieties. He has been followed by many strawberry breeders in England and on the Continent.

A fifth great character in strawberry history was Nicholas Longworth, a prominent horticulturist of Cincinnati, Ohio, and great-grandfather of Nicholas Longworth, the late Speaker of the United States House of Representatives (*11*, *12*). In spite of the work of Duchesne and a few others, few people in the United States knew there were different sex types in the strawberry. Longworth rediscovered these differences some time before 1834. He and his associates are said to have examined millions of strawberry flowers and classified plants into four groups—(1) pistillate, (2) hermaphrodite or perfect, (3) two rather rare classes having staminate flowers, and (4) a class having both pistillate and hermaphrodite flowers on the

Figure 3.—The Chilean strawberry (*Fragaria chiloensis*) as grown at Ambato, Ecuador, at an elevation of about 10,000 feet, where the rainfall is probably not over 15 inches a year. This is thought to be the same variety of strawberry that Frezier took to Europe in 1712 and that was grown by the Indians in Chile when Columbus discovered America.

same plant. Longworth found that not over one-third of the flowers of the hermaphrodite varieties ever set fruit, while all, or usually all, of the flowers of pistillate varieties set fruit. Longworth's work eliminated one great cause of failure in commercial berry production and made it possible to raise strawberries much more widely than before. Though the difference between pistillate and so-called perfect-flowered varieties has been common knowledge since the time of Longworth, much of his work on the degree of sterility of the

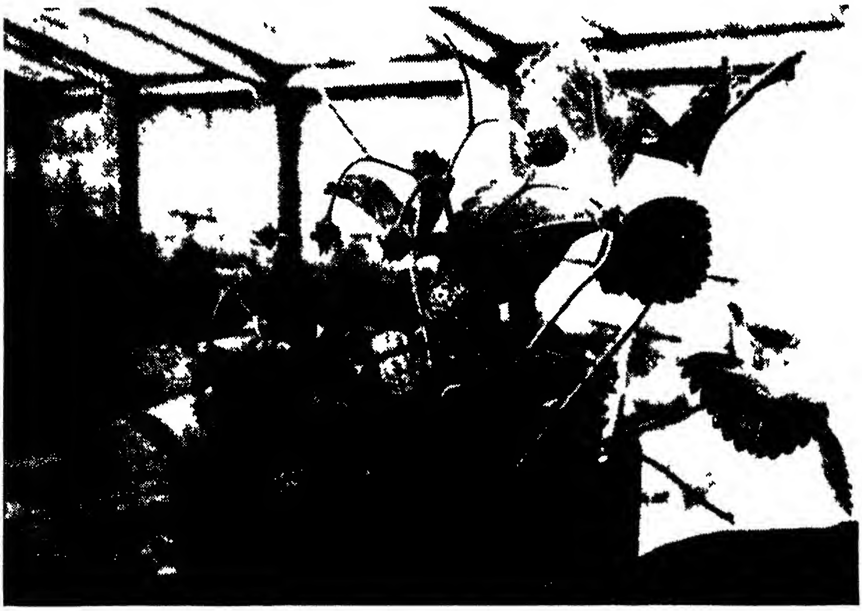

Figure 4.—The same variety of *Fragaria chiloensis* as in figure 3 but grown in a greenhouse near Washington, D. C., showing differences in shape and position of calyx (cap or hull). These berries were soft, while those shown in figure 3, grown in a cool, dry climate at a high elevation, are the firmest of any strawberries known in the world.

perfect-flowered varieties was lost sight of until rather recently, when it was rediscovered by Valleau (*60*) of Minnesota

Origin of American Varieties

The varieties originated in Europe were soon introduced into the United States, and many of them were grown extensively in this country, especially in the years before 1850. Commercial strawberry growing near the largest cities had begun in the United States about 1800, with such old varieties as Large Early Scarlet, Early Hudson, Hudson's Bay, Crimson Cone, Red Wood, and later the Hovey.

Since the time of Nicholas Longworth the outstanding development has been the introduction of a succession of new varieties with qualities that have made possible the extension of the territory where strawberries could be grown (*28*). Among the most important of these have been the Wilson, originated in 1851; Crescent in 1870; Sharpless

in 1872; Aroma in 1889; Dunlap and Marshall in 1890; Thompson in 1894; Klondike (*10*) about 1896; Missionary about 1900; Ettersburg 121 in 1907; Howard 17 in 1909; Progressive in 1908; Blakemore, Dorsett, and Fairfax in 1923; and Catskill in 1924 (*18*, *29*).

In England, Myatt introduced the British Queen in 1840, and Bradley originated the Sir Joseph Paxton in 1862 and introduced the Dr. Hogg in 1866. The Jucunda originated with Salter before 1860.

A large number of the other important English varieties were originated by Thomas Laxton and by his sons, the firm of Laxton Bros. With the encouragement of Darwin, Thomas Laxton began his strawberry breeding about 1865. His first variety was the Noble, introduced in 1884 and still grown extensively, especially in Germany and the Netherlands. In 1888 the King of the Earlies was introduced, and in 1892 the Royal Sovereign, a cross of Noble and King of the Earlies. Though British Queen and Dr. Hogg are the finest in quality in England, Royal Sovereign has high quality and is probably the most widely grown variety in northern Europe. Latest of All was introduced by Laxton Bros. in 1894, and Givons Prolific, raised by William Peters of Givons Gardens, was introduced in 1901. Bedford Champion was introduced by Laxton Bros. in 1904 and The Duke in 1919.

In France (*38*, *46*) Pelevain introduced Princess Royale in 1844, and it was said to have been the leading French variety for over 50 years. About 1856 the Vicomtesse H. de Thury, raised in 1845 by M. Jamin, was introduced; Marguerite was originated in 1859 by M. Lebreton; and in 1871 the Dr. Morere, raised by M. Berger, was introduced. Dr. Morere has been grown as widely in France as the Royal Sovereign in England.

In the Netherlands, Mme. Kooi was raised by G. Kooi before 1920 and introduced by R. Hendrikson, who also introduced the Mme. Lefèbre.

In Germany, Late Leopold, raised by L. Lierke, was introduced in 1904. Deutsch Evern, a cross of Sieger × Noble, was raised in 1902.

STRAWBERRY VARIETIES OF THE WORLD[3]

United States

A great many varieties have been grown in the United States, but at present only about 30 are important, 20 of them in about the order shown in table 1.

Besides the 20 listed, 11 other varieties make up about 4 percent of the total acreage (*18*). These varieties, with the same abbreviations for origin as in the table, are Catskill (Br), Clark (Br), Oelrich (Ulrich) (Ch), Ettersburg 121 (Br), Corvallis (Br), Glen Mary (Ch), Ridgely (Ch), Sample (Ch), Clermont (Br), Fairfax (Br), and Narcissa (Br). Though there are many other varieties in the trade, they are grown to a very limited extent.

Twenty-two of the thirty-one varieties were originated as the result of breeding, and they constitute over 75 percent of the acreage (*18*, *32*). For the most part, each of the important varieties has

[3] The strawberry species are described and listed in the appendix.

made its way rather quickly into a prominent position. Growers generally are interested in testing new sorts and are ready to change to any promising new variety. For example, the Howard 17 was introduced under that name in 1918, and 10 years later it was the principal variety north of the Ohio and Potomac Rivers. The Dorsett, introduced in 1933, has already become well known on the larger markets of the Eastern States.

TABLE 1.—*Important strawberry varieties grown in the United States*

Rank	Variety	Total acreage	Origin [1]	Approximate date introduced (i) or originated (o)
		Percent		
1	Klondike	30.0	Br-Pri	1890 (o).
2	Howard 17 (Premier)	16.0	Br-Pri	1918 (i).
3	Aroma	10.0	Br-Pri	1889 (o).
4	Blakemore	8.0	Br-Pub	1923 (o).
5	Missionary	7.0	Ch	1900 (o).
6	Marshall	7.0	Ch	1890 (o).
7	Dunlap	3.5	Br-Pri	1890 (o).
8	Chesapeake	2.0	Ch	1903 (o).
9	Joe	2.0	Br-Pri	1899 (i).
10	Dorsett	2.0	Br-Pub	1923 (o).
11	Aberdeen	1.0	Br-Pri	1909 (o).
12	Lupton	1.0	Br-Pri	1905 (o).
13	Heflin	1.0		1902 (i).

19	Mastodon	.5	Br-Pri	1917 (o).
20	Parsons (Pocomoke)	.5	Ch	1890 (o).
	Other varieties	4.0		

[1] Br=breeding; Pri=private agency; Pub=public agency; Ch=chance seedling.

The varieties now used probably represent better adaptation to conditions in the regions where they are grown than former sorts. Varieties such as Missionary, Klondike, Dunlap, and Heflin are more like the wild meadow strawberry of eastern North America than like the beach strawberry. Through the hundred years of evolution in the cultivated strawberry the varieties have been tending toward the native eastern wild strawberry. This has occurred because (1) most varieties have originated in the East; (2) seedlings with more of the characteristics of native wild strawberry have naturally succeeded best and have been selected by breeders; and (3) many varieties, such as Missionary, were found in the wild as chance seedlings. The latter may have originated either from seed of cultivated varieties or as the result of bees carrying pollen of cultivated sorts to the native strawberry. In some regions along the Atlantic coast most of the strawberries found growing wild are now in part derived from cultivated sorts. Natural crossing of cultivated with the beach and the Rocky Mountain strawberries has already started in the Western States, and many natural crosses have been found there.

Fairfax, of the eastern varieties, and Ettersburg 80 and 121, of the western varieties, are the nearest to an intermediate between the eastern meadow strawberry and the beach strawberry. Dorsett (fig.

5), Howard 17, Chesapeake, and Marshall are thinner leaved and thus somewhat closer to the Missionary, Klondike, and Dunlap group. The success of Etter (*8*) and Georgeson (*30*) whose work will be discussed later, in using selections of the beach strawberry has revived interest in this species. It is now being used extensively, particularly in the California and the United States Department of Agriculture breeding work, to increase vigor and to obtain resistance to root rots. Hybrids of cultivated varieties with *Fragaria chiloensis*, the beach strawberry, have much greater vigor than most variety crosses. It

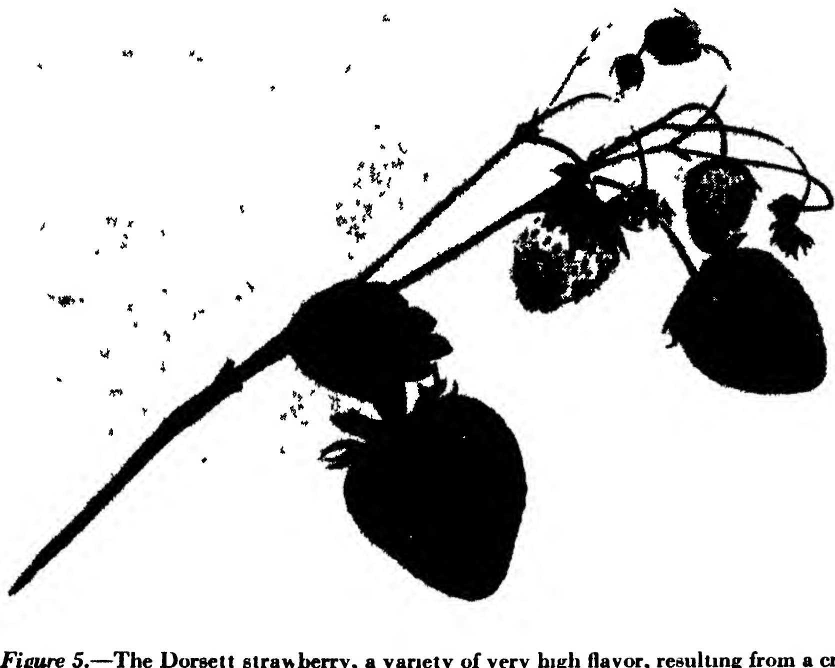

Figure 5.—The Dorsett strawberry, a variety of very high flavor, resulting from a cross of Howard 17, which is the principal variety of the northeastern United States, and Royal Sovereign, long the standard of excellence in northern Europe.

appears that through the scores of years since the strawberry came back from Europe some inbreeding has occurred that has lessened the vigor of the cultivated strawberry.

Important Varieties in Foreign Countries

The strawberries of Canada are similar to those of the United States, the varieties being the same in most instances. In eastern Canada, Dunlap, Parsons, Howard 17, and Glen Mary are the chief sorts. In British Columbia, British Sovereign, Magoon, Marshall, and Sir Joseph Paxton are raised in the milder coast climate, and Dunlap, Glen Mary, and Parsons (Gibson) in the interior.

Because wild parental types of the cultivated strawberry are not native to Europe, Asia, Africa, or Australasia, varieties of these countries are all, or nearly all, the result of breeding. The varieties so

developed differ from one another more than do American sorts. The principal varieties grown in each country are as follows:

England.—Royal Sovereign, Mme. Lefèbre, Late Leopold, Oberschlesien, and Huxley (probably Ettersburg 80). The Duke, Sir Joseph Paxton, Bedford Champion, and Mme. Kooi are being grown somewhat, and Western Queen and Pillnitz are being tested.

Scotland.—Scarlet Queen, John Ruskin, Royal Sovereign, MacMahon, and The Duke.

Germany.—Deutsch Evern and Noble for early, Sieger, Oberschlesien, and Roter Elefant for midseason, and Jucunda and Leopold for late. Vierlanden is raised near Hamburg.

Netherlands.—Jucunda, Deutsch Evern, and Noble, with some Scarlet and Oberschlesien.

France.—Minerve, Souveraine, Moutot, V. H. de'Thury, Dr. Morere, Paxton, Tomate, Marguerite, Leopold, and others.

Norway.—Deutsch Evern, Abundance, and Bedford Champion.

New Zealand.—Marguerite, Melba, Ettersburg (80 or 121?), Captain Cook, Noble, Helenslea, Surprise, and Royal Sovereign.

Victoria.—Melba and Wilson's Pride.

Tasmania.—Ettersburg (80 or 121?), Royal Sovereign, Melba, and Abundance.

STRAWBERRIES FROM SEED

The varieties of cultivated strawberries of the United States do not come true from seed. If 1,000 seeds of Marshall or Klondike or Howard 17 are planted, no 2 seedlings will be exactly alike. Some plants will be weak, some strong; some will make few runners, some many; some will have large fruit, some small; some will be productive, some unproductive. Out of the thousand, few if any will be as good as the parent. Because they do not come true from seed, and because they are so easily propagated by runners that root at the tip to form a new plant, all American varieties are propagated in this way, never by seed.

In Europe there are a few cultivated varieties called alpines or everbearing wood strawberries, some of which are often and others of which are always raised from seed. They produce much smaller fruit than do our cultivated varieties and are closely related to the wood strawberries of North America. Thus, the Bush White is an alpine variety that makes no runners, has small, white fruit, and, because it makes no runners, is always raised from seed. The Belle de Meaux is an alpine that produces runners, has red fruit, and may be raised from seed or propagated by runners. Such varieties have been selected, as have vegetables and other seed-propagated plants, until they come approximately true from seed. Seed varieties of alpines are relatively easy to establish as compared with seed varieties of the common cultivated strawberry. However, these alpine varieties are rarely grown in the United States.

Though it is extremely unlikely that any one of 1,000 seedlings of Marshall, Klondike, or Howard 17 will be better than its parent, breeders have learned that if Marshall is crossed with some other variety and 1,000 seedlings are raised, the progeny will be far more vigorous and productive than seedlings of Marshall that are not the result of crossing. Thus, from a cross between Marshall and Howard 17, Slate, at the New York (State) Agricultural Experiment Station, raised 1,132 seedlings and saved over 150 as especially promising (*55*).

From these he selected a seedling that he named Catskill, which combines many of the good qualities of both parents. It is now widely grown.

FLOWER TYPES IN STRAWBERRIES

Cultivated strawberries produce two general types of flowers—pistillate, and perfect or hermaphrodite (*11, 18*). Pistillate flowers contain pistils, the female parts, but no stamens, while perfect or hermaphrodite flowers contain both pistils and stamens, the male parts. The other two types of plants, staminate and that with both pistillate and perfect flowers on the same plants, are rare. Pollen is

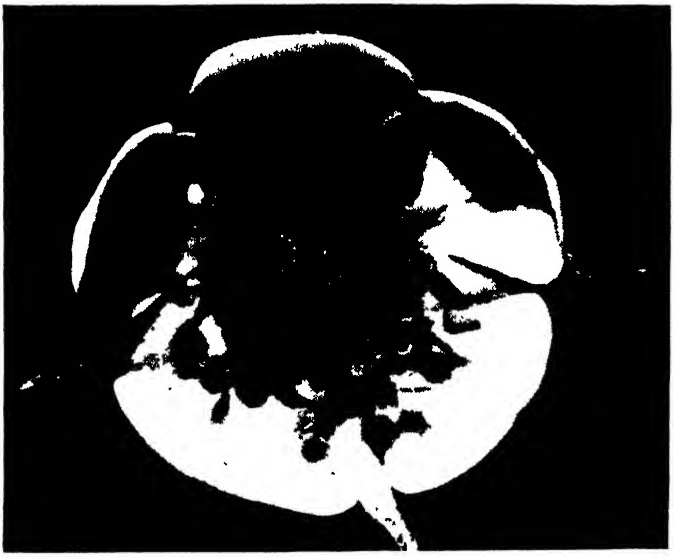

Figure 6.—A strawberry flower showing the pistils in the center surrounded by stamens. The anthers at the ends of the stamens are cracking open around the edges and shedding pollen.

carried by bees and other insects, but it is also thrown out of the stamens as the anthers crack open (fig. 6), or it is jarred out and blown by the wind and falls on the pistils. A variety having perfect or hermaphrodite flowers can produce fruit when planted by itself, but one with pistillate flowers cannot set fruit unless perfect-flowered plants are nearby to furnish pollen through the agency of bees or other insects. Because of this, varieties having pistillate flowers are not generally so desirable as those having perfect flowers, and few of them are grown now. However, some of these pistillate varieties are very productive. Pistillate varieties are also injured less by the strawberry bud weevil than perfect sorts, since this insect feeds on pollen; and in regions where it is serious, pistillate sorts are still grown. When the plants are in flower it is very easy to tell a pistillate from a perfect-flowered variety, as illustrated in figure 7.

Partial Sterility of Perfect-Flowered Varieties

Though the flowers of pistillate varieties nearly always set fruit when pollinated, those of perfect-flowered varieties rarely all set fruit. The flower may appear to be normal, but the pistils may be sterile. Under some conditions not 1 in 50 of the flowers of certain varieties sets fruit. Studies by Valleau (*60*) have shown that only the pistillate plants of the wild meadow, beach, and mountain strawberries set fruit. Perfect-flowered plants in the wild are in reality males, even though the pistils usually appear normal. Occasionally the first flower to open on a wild perfect-flowered plant may set a berry, and very, very rarely

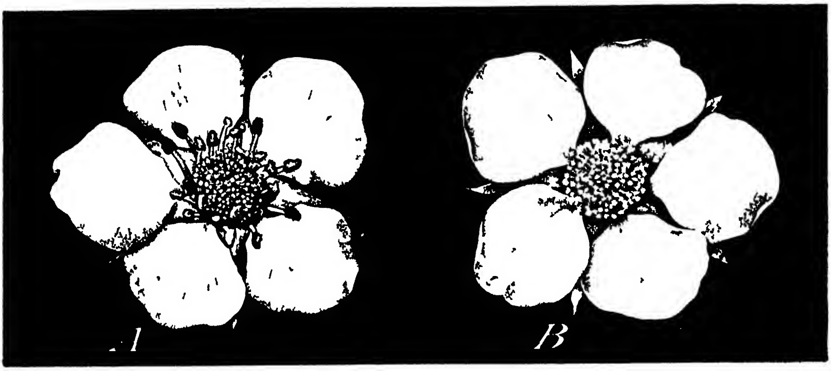

Figure 7.—A perfect or hermaphrodite strawberry flower (*A*) having both pistils and stamens, and a pistillate flower (*B*) having pistils but no stamens. Pistillate varieties will not produce fruit unless they are grown near plants having perfect or pollen-producing blossoms so that bees can carry the pollen to the pistillate flowers.

most of the perfect flowers on a plant of the wild meadow strawberry may set fruit.

The first flowers to open on a cluster of a perfect-flowered variety are more likely to set fruit than the later ones, and the last ones to open are most often sterile. On the average about one-third of the blossoms of cultivated perfect-flowered varieties are sterile. The clusters produced by the main crown of a plant have fewer sterile flowers than the later-formed clusters of branch crowns. Through scores of years, by breeding and selection, perfect-flowered varieties have now been obtained that set nearly all their flowers. In fact, under favorable conditions all the flowers of the Rockhill everbearing seem to set.

At its base the pistil contains a minute egg cell ready for fertilization when the flower opens. After pollen is placed on the end of the pistil, one or many of the pollen grains start to grow a tube down the center of the pistil. The pollen absorbs food from the tissues of the pistil, and finally one pollen tube reaches the egg cell. The sperm nucleus, a minute globular mass in the pollen grain, passes down the pollen tube, enters the egg cell, and unites with the egg nucleus. When the nuclei of the pollen and egg unite they form a single cell that is the germ of a new plant. By successive divisions of this original cell, the

embryo plant, contained in the seed that we see on the outside of the strawberry, is finally formed. Within a few hours after the pollen and egg nuclei unite, the ends of the pistils dry up. If no pollen reaches the ends of the pistils they will not dry up nearly so quickly. After the embryo has started to grow, the tissue around the seed starts to develop into what we call the strawberry. If any pistil is not pollinated, then the tissue around the base of that pistil does not develop. When the pistils on one side or part of a flower have not been pollinated or have been damaged by frost, the result is a misshapen berry.

TECHNIQUE OF BREEDING STRAWBERRIES (*19, 20*)

Crossing of strawberries may be done in the field under cages of wire screen or cloth or under sun traps (fig. 8, *A*). Making large numbers of crosses in the field is very laborious and must be done within a short time. Flowers may be killed by unseasonable late frosts, so that the work has to be repeated and time is lost. For these reasons, if facilities are available the crossing should be done in greenhouses, either heated or unheated (fig. 8, *B*).

The other advantages of using an unheated greenhouse are that (1) the flowers open about a month earlier than in the field; (2) it is possible to stand erect or sit while doing the crossing; (3) the pots can be carried to different parts of the greenhouse to save time; (4) insects usually do not interfere, so that the plants do not need to be covered; (5) the stamens do not open before the petals unfold, which makes it possible to emasculate and pollinate at the same time, while many stamens shed pollen before the flowers open out of doors; and (6) many perfect-flowered varieties produce primary, secondary, and even tertiary flowers having no pollen-bearing stamens, so that emasculation of such flowers is unnecessary, yet out of doors most flowers of the same varieties produce good stamens. Plants may be potted any time during the fall or winter for bringing into such an unheated greenhouse.

Pollination

In emasculating, the thumbnail is generally used to cut away the stamens, corolla, and calyx at one operation (fig. 9, *A*). If this is done with ordinary care, no injury to the pistils follows. Often the calyx and corolla are removed to identify crossed flowers even though emasculation is not necessary. The primary and secondary flowers, the first and second to open, contain far more pistils than the flowers opening later in a cluster. Berries developing from the primary and secondary flowers can set far more seed than the later berries, hence every effort is made to pollinate the earliest flowers on each cluster.

In crossing, the flowers having unopened pollen-bearing stamens are picked and allowed to wilt until the anthers crack open to let the pollen out. The flowers are used directly on those to be crossed, being held so that the stamens touch the pistils. The flower is then twirled by its stem so as to cover all the ends of the pistils with pollen (fig. 9, *B*). A flower with abundant pollen may be used to pollinate four

138904°—37——30

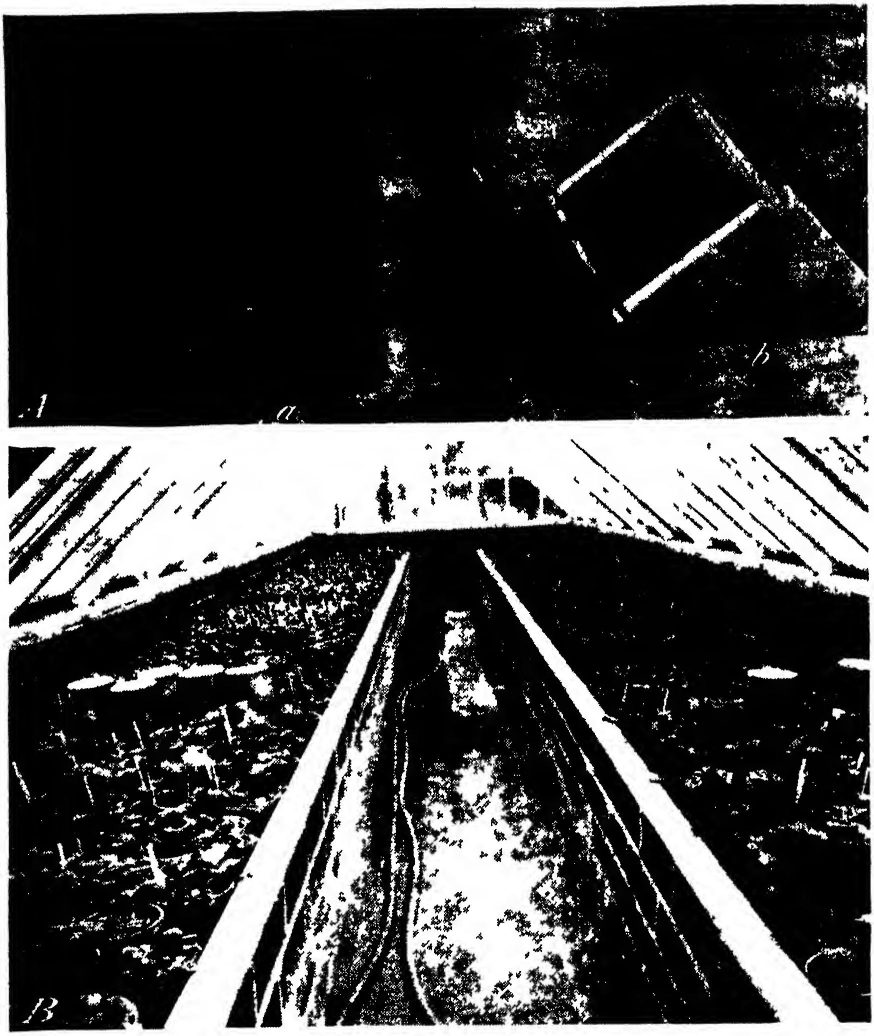

Figure 8.—*A*, Types of coverings formerly used to keep insects away from flowers that were being crossed in the field: *a*, A wire screen cage; *b*, a glass sun trap. In recent years the work has been done far more quickly and safely in cold greenhouses or propagating houses, as shown in *B*. *B*, Interior of a cold greenhouse at the breeding season. Note that the benches are of solid earth and that the center walk is below the ground level. The house is of the simplest construction, being made of coldframe sash. The potted plants of the different varieties to be used in breeding have started spring growth, and most of the crossing can be done before the flowers start on plants out of doors.

to six flowers or even more. Some breeders collect pollen and then use small brushes to apply it.

After being pollinated, the flower, flower cluster, or plant is marked to indicate the cross (fig. 10) and then bagged or protected in some

Figure 9.—Crossing the strawberry: *A*, Flowers being prepared for crossing. The petals, sepals, and stamens are removed by cutting them off with the thumbnail. *B*, Flowers being pollinated. The flower of the variety to be used as a male parent is being pressed against the pistils and the flower twirled between the fingers to brush the pollen onto the pistils.

way from insects if necessary (fig. 8, *A*). The berries are picked as soon as they are fully mature. The fresh berries may be mashed in dry sand to separate the seed, and the mixture of seed, pulp, and sand is sowed in flats and pots at once They are then covered with about one-eighth of an inch of sand, and at no time is the seed allowed to become dry. With temperatures from 60° to 80° F., the seed germinates in a few days. With very high temperature the seed may become dormant and stay dormant until after a period of cold weather. Soil to which commercial fertilizer has been added should not be used, for it may prevent germination.

Figure 10.—A pistillate variety used in breeding. The petals and sepals were removed from the flowers when they were pollinated in order to identify them. The label indicates that all 24 flowers were pollinated with U. S. D. A. selection no. 632 (Redheart).

Handling the Seedlings

When they reach a size convenient for handling (fig. 11), the seedlings are pricked either into flats 2 inches apart or into thumb pots. As soon as they are large enough (2 to 4 weeks) they are set in the field. If set in the field in Maryland by July 1 they should produce a good crop the next spring. The plants may be set 4 to 5 feet apart and allowed to make a small mat of runner plants, or 12 to 18 inches apart in the row and all runners kept off.

Selection of Seedlings

At the beginning of the ripening season, all plants that would not be desirable commercially, including dwarfs and those subject to leaf or root diseases, may be cut out. Further selection when fruit characters are judged will then be easier. The number of selections made for future testing varies greatly but is rarely over 10 percent and is usually less than 2 percent of the plants fruited (fig. 12). The

selections are then propagated and a second test on a larger scale, either a 25- or a 50-foot row, is made in comparison with standard varieties. After the second test some selections may be tested further for some special quality such as suitability for preserving, canning, or shipping, or for behavior in different regions of the country.

STRAWBERRY BREEDING IN THE UNITED STATES

Objectives

THE FINE dessert quality and the extensive cultivation of the strawberry today are a tribute to the ability and industry of breeders of

Figure 11.—Strawberry plants grown from seed. The five seedlings at the left are the proper size for repotting; the one at the right is larger than the usual size.

the past century and a half. Further improvement may consist largely in obtaining varieties with (1) greater resistance to leaf, crown, and root diseases, to the virus diseases, and possibly to insects and nemas (eelworms); (2) greater resistance to high and low temperatures and to drought; (3) better adaptation to long and short days (*17*); (4) better dessert quality under adverse weather conditions; (5) increased firmness and toughness of skin; and (6) better adaptation to specific uses such as deep red, firm, tart varieties for canning; varieties holding their shape, texture, flavor, and color after freezing; light red but red to the center, tart, firm ones for preserving (*15*); varieties with aroma suitable for flavoring, etc. Such improvements would lessen the risks now faced in growing strawberries. Varieties most desirable for freezing for the small-package trade have been found too subject to diseases or not productive enough to become commercial sorts. Southern varieties have been highly acid and without much aroma in cold and unfavorable weather, yet there are varieties that have high flavor under such conditions.

Methods of Breeding

So far, improvement has come through direct crossing of varieties and species and backcrossing to the parents. Crossing and the raising of large numbers of seedlings is relatively easy and has been a rapid and effective method of breeding. Backcrossing a seedling to one of its parents has long been used by strawberry breeders as a regular practice. There is much that can probably still by done by these methods. However, with new problems, new methods, and new

Figure 12.—After "Judgment Day" in the strawberry field. This photograph shows what is left after selection has been completed. The seedlings that have been found wanting have been destroyed, and of the thousands of plants originally in the field only a few remain.

facilities, plant-breeding practices may change. The sporting of Blakemore, Howard 17, and other varieties to yellow plants may make new methods useful.[4] Sporting to yellow leaves seems to be due to the appearance of recessive characters. Because this yellow plant is worthless, a method needs to be devised for eliminating its inheritance from breeding stock and from varieties to be introduced.

The use of selfing to obtain relatively pure lines has not been satisfactorily explored, though some selfing has been done by several breeders. When selfing has proceeded for two or three generations, the plants are not vigorous and may be easily lost. Only under very favorable conditions can they be kept alive. For this reason, little information on this method is yet available. Yet immunity from or high resistance to leaf spot or other diseases may be due to recessive

[4] Darrow, G. M Notes on variegated leaf troubles of strawberries U S Bur Plant Indus Plant Disease Reptr 18 26-29 1934

genes and appear only after inbreeding. Yellow leaf seems to be a recessive character that might be eliminated by selfing and by selecting selfed lines that do not carry it.

Private Breeders

Of the private breeders who produced varieties previously listed, the following are still living: A. F. Etter, Ettersburg, Calif., originator of Ettersburg 121 and other varieties; E. C. Howard, Belchertown, Mass., who was associated with his father in the origination of Howard 17 and Howard Supreme varieties; Harlow Rockhill, Conrad, Iowa, originator of Rockhill and Progressive, everbearing varieties; and Jeff Beaver & Son, Eau Claire, Wis., originators of Beaver. Other private breeders are Horace Wray, White Salmon, Wash., originator of Wray Red; and W. Kosuga, Sandy, Utah, originator of Berri Supreme.

These breeders made crosses and selected the seedlings that seemed to come nearest their ideal. Some of them have kept detailed records of their work, as the following parentage of Howard 17 shows:

$$\text{Howard 17}\left\{\begin{array}{l}\text{Seedling no. 1 of Howard}\left\{\begin{array}{l}\text{Seedling no. 4 of Howard}\left\{\begin{array}{l}\text{Haverland}\\ \text{Belmont}\end{array}\right.\\ \text{Clyde}\end{array}\right.\\ \text{Crescent}\end{array}\right.$$

The Howards tried to recombine in one variety the desirable qualities in several. Slate (*55*) has stated that Howard 17 is the outstanding parent used at the New York station. It has also been an exceptional parent in the breeding work of the United States Department of Agriculture.

A. F. Etter (fig. 13) has collected and used selected wild strawberries in his breeding work, which began about 1885 (*8*). His most valuable contribution has been this use of selections from the wild. Most of the 50 or more varieties introduced by him are derived from selections of the beach strawberry, *Fragaria chiloensis*, crossed with cultivated varieties. Qualities that he has bred into strawberry varieties through use of selections of the beach strawberry are being extensively used by other breeders. Thus, Redheart is a cross of Portia × Euresko, the latter being one of Etter's varieties. Southland resulted from a cross of Howard 17 × Ettersburg 80, while Corvallis is a cross of Marshall × Ettersburg 121. Many selections at experiment stations resulting from breeding work and under test at present have as one parent one of the Etter varieties or a variety or selection derived in part from his varieties.

Harlow Rockhill began his work with the everbearing strawberries in 1895 and has used both American and European sorts in his breeding. Progressive was his first production to be widely grown. His later variety, Rockhill (Wayzata), is resistant to cold and to leaf diseases and is one of the highest in dessert quality in the United States (fig. 14).

Federal Strawberry-Breeding Work

The Federal strawberry-breeding work (*19*, *20*) has been carried on in Maryland since 1920. The work was extended in 1928 to include cooperative work at the North Carolina Coastal Plain Branch Station at Willard and the Oregon Agricultural Experiment Station at Corvallis.

Over 86,000 seedlings, representing hundreds of crosses, have been fruited at Glenn Dale, Md., and at United States Horticultural Station, National Agricultural Research Center, Beltsville, Md. In all, over 150 varieties and 20 selections of species have been used in this breeding work. Selections to the number of 1,999 have been made, 7 varieties have been named and introduced, while 342 selections are still unnamed and are being held for further testing or for breeding.

The first work at Willard consisted of tests of selections from the Glenn Dale station. Beginning in 1929, small seedlings raised in Maryland were taken to Willard and fruited there. Since the beginning about 54,000 seedlings have been grown at Willard and 1,245 selections have been made. No selections have been named, though several are being extensively tested and propagated. The crosses have been made especially to obtain firmer, higher flavored shipping varieties for the South.

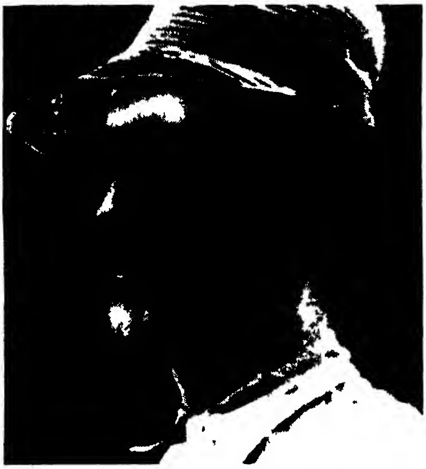

Figure 13.—A. F. Etter, Ettersburg, Calif., pioneer in the use of native western strawberries, plums, apples, and gooseberries. Not only have his varieties been widely grown, but other breeders have used them extensively in their breeding work.

At the Oregon station the first work also consisted of tests of selections made in Maryland. However, crossing was immediately begun, and to date some 97,000 seedlings have been fruited and 1,331 selections made. No selections have yet been named, though many are being extensively tested. The crosses made have been largely to obtain better preserving, freezing, canning, and shipping berries.

At the United States Horticultural Field Station, Cheyenne, Wyo., the first selections of the wild Rocky Mountain strawberry, *Fragaria cuneifolia* Nutt., were made in 1935. Though small fruited, they proved much hardier than cultivated varieties, and in 1936 over 30,000 plants were collected, chiefly from the States of Wyoming, Colorado, Utah, Montana, and South Dakota. Selections of these are to be used by Powers and Hildreth in crossing to produce varieties more resistant to cold, dry winters.

Extensive tests of many of the selections at Willard, N. C., have been made in Maryland and at Corvallis, Oreg., to find some especially adapted to freezing in small packages with sugar or sirup. Similar tests have been made of the preserving and canning qualities of many varieties. As a result of this work, the Blakemore was selected early in the breeding work for its superior qualities for the making of preserves (*15*). It is considered the best of all varieties for this purpose in the United States. The Redheart was selected for its canning qualities and is now raised more extensively than any other canning variety. Breeding for firmness and adaptation to short day

length requirements at the Willard station have been other objectives Some of the crosses that have some of these desirable qualities are listed in the appendix under Sources of Superior Qualities in Strawberries

Studies on the sterility of flowers (*12*), types of flower clusters (*13*), number and length of runners, stomata of the leaves (*14*), transpiration from the leaves, fruit-bud development (*6*), spacing of plants, and leaf area in the late fall have shown just what plant characteristics are most desirable and why. Thus, the fertility of all the flowers of Rockhill, the low-branching fruit clusters and early fruit-bud initiation

Figure 14.—The Rockhill everbearing variety (*A*) contrasted with a variety of the Alpine everbearing (*Fragaria vesca semperflorens*) (*B*). Note the much smaller fruit of the latter.

of Howard 17, the long, large runner and natural spacing of plants of Fairfax, the type of stomata of Blakemore (*14*), and the extensive leaf area of Dorsett when spaced—these have been found to be desirable characteristics under some conditions and useful in breeding. In fact, an intimate and extensive knowledge of such characteristics in varieties is of great importance in selecting varieties for breeding and in making selections from seedling fields.

Strawberry Breeding at State Experiment Stations

Extensive strawberry breeding is a part of the work at many State experiment stations. A list of the workers at these stations and the locations of their work is given in the appendix.

A relatively small part of the total strawberry acreage of the country—about 10 percent—consists of varieties originated by public

agencies. However, the acreage of Catskill, Dorsett, Fairfax, and other new introductions is increasing rapidly, and these varieties are becoming important commercial sorts. Strawberry breeding has been started only recently at many experiment stations as the need for better varieties has become apparent. Results from much of this work are not yet, of course, in the trade.

Alaska

Strawberry breeding was begun in Alaska (*30*) in 1905, the first crosses being made between cultivated varieties and selections of the beach strawberry, *Fragaria chiloensis*. Later, selections of the hardy interior wild strawberry, *F. cuneifolia* (*F. platypetala* Rydb.), as well as numbered seedlings, were also used in crossing. Named varieties from the States do not succeed in the climate of Alaska, and crosses were made to obtain varieties with the size and productiveness of the cultivated varieties and the hardiness of the native wild strawberries. Some of the resulting hybrids were found to be hardy at Fairbanks, in the interior of Alaska, where extremely low temperatures occur in winter and where there is continuous daylight for about 2 months in summer. Up to 1922 some 11,600 seedlings had been raised. As a result of this breeding work strawberries are now commonly grown in Alaska. Since about 1922, varieties originating at the experiment station at Sitka have supplied the markets both on the coast and in the interior, even above the Arctic Circle.

Minnesota

Strawberry breeding in Minnesota was begun in 1908 and has continued to the present. The earlier work consisted of crosses between commercial varieties to obtain hardier sorts. Between 75,000 and 100,000 seedlings were raised from 1909 to 1924. Seven varieties were named and introduced as the result of this work—Duluth and Deephaven as everbearing sorts, and Minnesota, Minnehaha, Chaska, Easypicker, and Nokomis as early summer sorts. The principal varieties used as parents were Abington, Autumn, Beder Wood, Brandywine, Clyde, Crescent(?), Duluth, Dunlap, Easypicker, Enhance, Golden Gate, Jessie, Margaret, Pan American, Prolific, and Sheppard. Similar work on a smaller scale has been continued since 1927.

Selection within self-fertilized lines was begun in 1922 and is being continued. Varieties selected for desirable characters are self-pollinated, about 5 percent of the better seedlings propagated, compared, and the superior lines again selfed. Lines that have been selfed for one, two, and three generations are now being grown. The principal varieties used in this work are Belt, Chaska, Dunlap, Howard 17, Marshall, and Minnehaha, and to some extent Beaver, Duluth, Early Bird, Mastodon, Minnesota, and Progressive.

South Dakota

The breeding work in South Dakota (*31*) has consisted of an attempt to introduce into the cultivated strawberry the hardiness of the native strawberry of the Dakotas. Dakota No. 1 and Dakota No. 2 were

introduced, and the former, now known as Dakota, is perhaps the hardiest variety known in the United States.

California

The breeding work in California was begun by W. T. Horne and A. G. Plakidas in 1925–26 to obtain varieties resistant to the yellows or xanthosis virus disease. In recent years the work has been carried on by E. V. Goldsmith and H. E. Thomas, and resistance to phytophthora root rot has been made a second major objective. Varieties and selections obtained from A. F. Etter and the United States Department of Agriculture, as well as many commercial varieties, have been extensively used. Among the desirable characters for California conditions not necessarily considered elsewhere are longevity of plant, open crowns, long inflorescences, small seeds, and heavy production in spring, summer, and fall. The work has centered at San Jose until recently, when part of it was transferred to Davis. Though very large numbers of seedlings have been raised and many selections made, no varieties have yet been named and introduced.

New Jersey

Breeding work at the New Jersey Agricultural Experiment Station (*7*) was begun in 1928 and has continued to the present. All available varieties having promise for New Jersey conditions, as well as many unnamed selections from other institutions carrying on strawberry breeding, have been tested. The principal varieties used include Aberdeen, Berri Supreme, Bliss, Bouquet, Chesapeake, Dorsett, Fairfax, Gandy, Howard 17, Lupton, Mastodon, Parcell, Pearl, Redheart, Teddy Roosevelt, Wyona, and U. S. D. A. 854 and 875. Besides published data on inheritance of earliness and lateness, data have been obtained on sex ratios, shape, color, flavor, and firmness of berry, and on inheritance of the everbearing characteristic. One variety, N. J. 35, was introduced in 1936. Lupton transmitted its size and attractiveness but also its poor quality to its seedlings. Chesapeake transmitted its good flavor and its unproductiveness. Many of the best very late ripening seedlings have had Pearl as one parent. Fairfax seedlings have had high flavor and were exceptionally firm.

New York

Strawberry breeding at the New York station at Geneva was begun in 1889 by C. J. Hunn and has been continued at intervals ever since (*1*, *2*, *54*). At least 68 named varieties, as well as many selections from crosses, have been used in the breeding work. Over 13,000 seedlings have been raised and 21 varieties have been introduced. Several of the more recent introductions are grown to a slight extent, chiefly in New York State. Clermont is grown to a considerable extent in Erie and Oswego Counties. Catskill, however, is rapidly becoming an important commercial variety from Maryland to Missouri and northward. Most of the introduced varieties have had Marshall or Howard 17 or both as a parent, Marshall contributing high flavor and large size of berry, and Howard 17 productiveness and disease resistance. In a summary of the best parents in the breeding work, the importance of Howard 17 as a parent is emphasized.

A large percentage of its seedlings produce very smooth, uniform-shaped, glossy berries that hold up well to the end of the season. A few selections of species have been used in crosses.

Connecticut

At the Connecticut station, Howard 17, Chesapeake, and Glen Mary were inbred for three generations and then the F_3 (third-generation) progeny were crossed. The strawberry was reported to respond to inbreeding and crossing in much the same way as corn. The F_3 plants were dwarfed, but crossing seemed to bring back the vigor that the varieties originally possessed. From about 9,000 seedlings that resulted from crossing the F_3, promising selections have been made and are being given field trials in different sections.

Other State Stations

At the Maine station, breeding work was begun in 1934 to obtain better late varieties. At the Massachusetts station, breeding work was also begun in 1934 to obtain late varieties of better dessert quality and also better pistillate sorts.

In Illinois, breeding work to obtain varieties resistant to brown stele root rot was started in 1935. Mastodon, Aberdeen, and Redheart, which appear resistant, have been used in crossing.

In Wisconsin, breeding was begun in 1933 to obtain productive early and late commercial sorts. Howard 17, Beaver, Corvallis, and Vanguard have been used as parents.

In Missouri, though some crossing was done at the Mountain Grove station in 1902 and 1919, no varieties were introduced. In 1936 selections of the meadow strawberry, *Fragaria virginiana*, were crossed with Aroma, Blakemore, Fairfax, Dorsett, Chesapeake, Howard 17, and Joe, to obtain varieties with the resistance to cold, drought, and disease, and the high flavor of the wild strawberry.

In North Dakota, small-fruit breeding began in 1920 and has continued to the present. The Dry Weather variety, resistant to drought, was introduced in 1928. Resistance to winter cold, summer heat, and drought is being emphasized.

In Tennessee, strawberry breeding began in 1923 and has continued to the present. Both selfing and crossing have been carried on to obtain productive varieties hardy in summer, resistant to leaf and root-rot diseases, and with attractive, firm, high-flavored berries suitable for processing and shipping. Some selfed seedlings of Aroma were found to be notably vigorous and productive.

At the Louisiana station breeding work has recently started with the objective of producing varieties resistant to leaf spot and scorch, of good shipping qualities, and sweeter than Klondike.

In Texas breeding work began in 1933 to obtain varieties resistant to heat, drought, and leaf spot, and that would produce sufficient runners under the climatic conditions of southern Texas.

In Washington State, at Puyallup, strawberry breeding was begun in 1929 and has been continued to the present. The objectives have been firm- and soft-fruited, high- and low-yielding, and red- and light-fleshed varieties.

In Oregon, at Corvallis, breeding work has been carried on in cooperation with the Federal work since 1928. Previously, however, the Corvallis variety was originated by C. E. Schuster from a cross between Marshall and Ettersburg 121. Schuster noted that Ettersburg 121 transmitted its vegetative characteristics with remarkable uniformity.

STRAWBERRY BREEDING IN OTHER COUNTRIES [5]

Canada

The Central Experimental Farm of the Dominion of Canada at Ottawa and several of the provincial experiment stations, notably the Ontario Horticultural Experiment Station at Vineland, have carried on strawberry breeding more or less continuously for many years. Several recent selections made at Ottawa are being extensively tested (*21*). At Vineland some 30,000 seedlings of 300 crosses and 60 open and self pollinations were raised, 340 selections were made, and several named (*59*). Two, Vanguard and Vanduke, were grown to some extent at one time.

England

Among private breeders in England, the firm of Laxton Bros., at Bedford, has been prominent for its berry breeding for over 50 years, and the varieties of strawberries originated by the firm have long been important in Great Britain as well as on the continent of Europe, in Australasia, and in other parts of the world. Among these, Noble, Royal Sovereign, Scarlet Queen, Leader, Fillbasket, The Laxton, Latest, Bedford Champion, and The Duke have been particularly important varieties. Royal Sovereign is one of the parents of Dorsett and Narcissa and possibly of Fairfax (*16*) also.

Strawberry breeding by public agencies in England is being carried on at the Long Ashton Research Station, University of Bristol, at the Horticultural Research Station at East Malling, Kent, and at the John Innes Horticultural Institution, Merton. The earliest work was that by C. W. Richardson from 1910 to 1922, on inheritance of characteristics in the species having seven pairs of chromosomes and to some extent in cultivated varieties. Spinks carried on rather extensive breeding work at the Long Ashton station. By 1923 some 5,000 seedlings had been raised and 145 selections made. He noted that Leopold transmitted its resistance to aphids, that seedlings of Leopold × Royal Sovereign and President × British Queen were susceptible to mildew, but that seedlings of Leopold × Stirling Castle were resistant to both aphids and mildew. All seedlings of V. H. de Thury × The Earl and L. Gautier × White Perpetual were resistant to mildew, and only 1 in 60 seedlings of V. H. de Thury × King George was susceptible. The seedlings of Bedford Champion × King George, Leader × St. Antoine, and Fillbasket × Bedford Champion were the best flavored.

Germany

In Germany three stations are carrying on breeding work with strawberries. At the University Institute for Fruit Culture, in

[5] Reports have been received from H. Wenholz, Sydney, New South Wales; W. S. Rogers, East Malling Kent, England; M. B. Davis, Ottawa, Canada; and W. S. Strong, Vineland, Ontario, Canada. Lists of the workers and of the varieties from foreign stations are given in the appendix.

Berlin, quick- and early-ripening varieties with not too many flowers are being bred for forcing houses. At the Kaiser Wilhelm Institute in Müncheberg the breeding of large, productive, high-flavored everbearers has been started, and studies are being made on methods used in making selections, on inheritance and correlations of different qualities, on sex ratios, and on the periodicity of the growth phases. At the Horticultural Station at Pillnitz, under the direction of Professor Schindler, productive, high-flavored varieties that hold their color, that are resistant to unfavorable weather conditions, and that ship well are the objectives. Six varieties have been named and introduced from this station.

Australia

At the Hawkesbury Agricultural College, New South Wales, breeding for resistance to diseases such as root rot and leaf scorch is a primary objective. Seedlings of *Fragaria chiloensis* × British Sovereign, Fendalcino × British Sovereign, and Southland × British Sovereign have shown the most promise.

SUPERIOR GERM PLASM

In the strawberry, as in other plants and in animals, superior germ plasm refers to one or more inheritable qualities that may be desirable or useful to the grower or consumer. Thus, a variety or a species with fine flavor, or resistance to disease or to extremes of high or low temperature, would be counted as having superior germ plasm in that respect. Certain characters would be considered undesirable; for example, the one-flowered cluster of *Fragaria daltoniana* J. Gay.

Both of the species from which the common cultivated varieties are derived, *F. virginiana* and *F. chiloensis*, as well as *F. cuneifolia*, are extremely variable in the wild. Cultivated varieties, therefore, have various combinations of characters, desirable as well as undesirable. In general, the scarlet color, high aroma, tart flavor, and wide adaptation to climatic and soil conditions in cultivated varieties are derived from *F. virginiana*. The history of the strawberry and the success of Etter and Georgeson, who have used new selections of *F. chiloensis*, indicate that there may be many desirable characters in the wild forms of this species that have not yet been used. Tests of selections of *F. cuneifolia* and of hybrids with it indicate cold and drought resistance, everbearingness, and quickness of response to warm spring temperatures in this species (figs. 15 and 16). These desirable qualities might extend both the range of cultivation and the fruiting season of strawberries. As yet the collections and tests of *F. cuneifolia* are too limited to fully evaluate these and other qualities that it may have. However, hybrids of *F. cuneifolia* with cultivated varieties have made strawberry production possible even at Fairbanks, Alaska (*30*).

Because native species often are rather difficult to keep alive, crosses showing hybrid vigor may be useful in holding their superior germ plasm in breeding stock. *Fragaria chiloensis* is susceptible to cold injury in Maryland. Its hybrids with Fairfax and Blakemore are vigorous and are used as a source of the characters of *F. chiloensis* in the Federal breeding work. Because *F. cuneifolia* becomes everbearing at low elevations, it makes few runner plants, and for this

reason, too, hybrids serve as a source of its characters. Some of these hybrids and other selections having superior germ plasm are listed in the appendix.

Studies indicate that a variety or species showing any characteristic actually will transmit the character to a large proportion of its seedlings. Crosses of varieties and species, as well as genetic research, support the supposition that in the strawberry most qualities of importance in breeding are quantitatively inherited, that is, that there are genes for such qualities as flavor, color, size, firmness, etc., in each, or in many at least, of the eight homologous chromosomes

Figure 15.—The wild strawberry of the Rocky Mountains, *Fragaria cuneifolia.* So far it has been little used in breeding, but it is resistant to drought and cold and is everbearing when grown in Maryland.

(one pair in each four sets), and they have a cumulative effect. For example, it is as if the dark Redheart contained a gene for color in seven of the eight chromosomes, the less dark but still deep-red Dunlap in six of the eight, the medium-red Dorsett in five of the eight, the light-red Blakemore in four of the eight, and the White Sugar in about two of the eight. If Redheart is crossed with a dark-fruited variety, the seedlings are mostly dark-fruited; if it is crossed with a light-fruited variety, the seedlings are mostly intermediate.

In making crosses, therefore, breeders have learned that if a variety shows any desirable quality, in general that quality can be transferred to any other variety if a large enough number of seedlings (crosses between the two) are raised. Sometimes the seedlings nearest the ideal are backcrossed with one or the other parent before the desired character is obtained. The results published by Spinks (*57, 58*) and by Richardson (*50, 51*) in England indicate that it is easier to obtain many qualities in certain crosses than in others. Thus, Bedford Champion × King George V gave 80 productive seedlings out of 235,

while Royal Sovereign × King George V gave only 8 out of 114. Richardson obtained seedlings with the highest flavor from a cross of Filbert Pine × King of the Earlies. Until the genetic constitution of varieties is worked out, the location of superior germ plasm must be assumed to lie only in varieties that show it.

Because of the apparent quantitative inheritance of characters in the strawberry, a scoring system is used in the Federal breeding work to evaluate the qualities. A similar system was used by Keffer in Missouri in 1893. For flavor, color, firmness, resistance to leaf spot, resistance to leaf scorch, and vigor, seedlings are scored on a scale of

Figure 16.—Crosses of the Rocky Mountain strawberry, *Fragaria cuneifolia*, with the Marshall variety.

1 to 10, 1 representing best and 10 worst. Thus, at Beltsville, Md., Missionary might score 3 in resistance to leaf spot, Fairfax 1.5, Howard 17 also 1.5, Marshall about 8, and Beaver 8. For flavor, Dorsett would score 1, Howard 17 about 3, and Lupton 5. Richardson in England used such a scoring system for strawberries, although he used 1 as poor and 8 as finest in flavor. Since the vegetative cells of garden strawberries contain eight sets of chromosomes (seven to a set, $8 \times 7 = 56$ chromosomes), Richardson's scoring corresponds to the number of sets.

Though in years past it may not have seemed possible to have most of the desirable qualities of the strawberry in any one variety, it now seems practicable to get most qualities in breeding stocks and then cross these to obtain combinations of the qualities desirable for certain conditions. The history of the strawberry bears out this conclusion. Thus, the origination of the Wilson is considered to have made it possible to obtain varieties both firm-fruited and productive for different regions. The Howard 17 has added high resistance to diseases in Northern States to the superior germ plasm. Possibly within the next few years breeding stocks may have, in addition to

the fairly firm fruit, the productivity, and the disease resistance already obtained, (1) the cold-hardiness of the Progressive and of *Fragaria cuneifolia;* (2) the heat resistance of Missionary; (3) the drought resistance of *F. cuneifolia* and of U. S. D. A. 1791; (4) the smoothness of flesh of Corvallis; (5) the dessert quality of Rockhill in Minnesota and of Dorsett in Maryland; (6) the size of Marshall in the Pacific Northwest; and (7) the tough skin of Redheart. Later breeding may then add qualities for specific regions or uses, as the bright color of Blakemore for a preserving and shipping sort; the deep color of Redheart for a canning sort; the peculiar flavors—like grapes, apricots and red and black raspberries—of crosses of U. S. D. A. 652 for novelties; the short-day adaptation of the Missionary for Florida; the longer day adaptation of Howard 17 for other regions; and the everbearingness and runner production of Mastodon.

In Europe the source of superior germ plasm may also be indicated by the qualities for which outstanding varieties are known. Thus, British Queen and Dr. Hogg are considered to have the finest flavor, while Royal Sovereign and Paxton have the best flavor of the widely raised sorts; The Duke, an early, and Waterloo, a late variety, are often considered drought-resistant; Noble retains its color especially well in cooking and is one of the finest flavored and most widely adapted sorts; H. Vicomtesse de Thury (Stirling Castle), Deutsch Evern, and Little Scarlet are considered the best for jam and are very rich-flavored; Laxton's Latest, Late Leopold, Waterloo, and Givon's Prolific are very late sorts; Deutsch Evern and Royal Sovereign are superior forcing varieties; Mme. Kooi is very large and one of the most productive but is soft and of poor quality; Laxton's Latest is of the largest size; and Royal Sovereign, Sir Joseph Paxton, and Dr. Morere are widely grown, productive main-crop sorts, the Sir Joseph Paxton being frost-resistant. Late Leopold also escapes spring frosts. The Laxton grows where most other sorts do not succeed. Deutsch Evern is one of the best for preserving.

STRAWBERRY GENETICS AND CYTOLOGY [6]

There has been little satisfactory interpretation of the inheritance of characters in the strawberry, although there has been considerable study of the matter (*3, 4, 5, 6*). This is because most of the characters such as color, size, shape, and structure of berry are quantitative and determined by several genes. Three pairs of contrasting characters, however, are available for study.

Femaleness versus various degrees of hermaphroditeness has been extensively studied. In most cases when a hermaphrodite variety is selfed only hermaphrodite seedlings are obtained (*2, 9, 37*). Femaleness × hermaphroditeness gives in most cases at least a 1 to 1 ratio, apparently indicating a single pair of allelomorphs located in a single pair of chromosomes. However, hermaphroditic varieties and seedlings represent an unbroken series from complete fertility to complete sterility of the pistils, and a satisfactory genetic explanation is yet to be made. If the chromosome sets of the cultivated strawberry are not now identical, and if pairing takes place between chromosomes in different sets of seven, then more or less sterility would be expected.

[6] This section is written primarily for students or others professionally interested in breeding or genetics.

188904°—37——31

The unbroken series from complete sterility to complete fertility indicates that random pairing between all the chromosomes of all four sets actually occurs.

A second pair of contrasting characters is June-bearing versus everbearing. Everbearing varieties × everbearing varieties gave at Ottawa, Canada, 85 everbearing to 66 June-bearing, while everbearing × June-bearing and June-bearing × everbearing gave 257 everbearing to 788 June-bearing. The everbearing varieties are evidently heterozygous and the June-bearing homozygous. Assuming that everbearingness is due to two dominant complementary genes, *A* and *B*, then the everbearing would have the composition *AaBb* and, selfed, would give a 9 to 7 ratio, which was found, 85 everbearing to 66 June-bearing. When June-bearing are crossed with everbearing, a 1 to 3 ratio would be expected, or 261 everbearing to 783 June-bearing, which is very close to the 257 everbearing and 788 June-bearing actually found.

In England, Richardson selfed both the everbearer St. Antoine de Padoue, getting 108 everbearing to 22 June-bearing, and the everbearer Laxton Perpetual, getting 69 everbearing to 11 June-bearing. When he crossed a June-bearing Bedford Champion with an everbearing Laxton Perpetual he got 24 everbearing to 53 June-bearing. One of these June-bearing F_1 plants, when selfed, gave 8 June-bearing to 6 everbearing. These numbers indicate (1) that his everbearers did not have the same genetic constitution as those at Ottawa, Canada, and (2) that more than two and probably four complementary genes were involved, or that, if there were only two genes for everbearingness, they were linked. However, too few numbers have been raised for definite conclusions.

A third set of contrasting characters may possibly be useful in studies on inheritance, namely, normal versus variegated or chlorotic leaves. Richardson and Clark have made some studies on their inheritance. However, enough records have not yet been secured to indicate the genetic composition of a variegated plant.

Strawberry Species of the World

Although about 150 species names have been applied to the strawberry, the most recent monograph (*42*) described but 45, a number that is undoubtedly much too large. This monograph lists 4 species for Europe, 26 for North America, 1 for South America, and 15 for Asia. However, many of these can hardly be separated from one another and a total of about eight includes all the distinctive species. These eight belong to three groups as follows:

Fragaria vesca (wood strawberry) group, 7 pairs of chromosomes:
1. *F. daltoniana* J. Gay, southern Asia.
2. *F. nilgerrensis* Schlecht., southern Asia.
3. *F. vesca* L., circumpolar.
   Variety *semperflorens* Duch., Alps.
   F. californica[7] Cham. and Schlecht., North America.
4. *F. viridis* Duch. (*F. collina* Ehrh.), central Europe.

Fragaria moschata (open wood strawberry) group, 21 pairs of chromosomes:
5. *F. moschata* Duch. (*F. elatior* Ehrh.), central Europe.

Fragaria virginiana (cultivated strawberry) group, 28 pairs of chromosomes:
6. *F. chiloensis* (L.) Duch., coast of Alaska to central California, southern Chile, mountains of Hawaii.
7. *F. cuneifolia* Nutt. (*F. platypetala* Rydb.), Rocky Mountains.
8. *F. virginiana* Duch., eastern North America.

[7] *Fragaria californica* is very close to *F. vesca* and may be considered only a botanical variety of *F. vesca*.

Though these eight may include all the wild species, a final classification must await extended field studies of Asiatic forms. Six of the species are illustrated in figures 17 and 18.

Species With Seven Pairs of Chromosomes

The first four species have seven pairs of chromosomes (*40, 62, 64*) and are in general smaller plants with thinner leaves and smaller fruit than American cultivated varieties. *Fragaria daltoniana*, *F. collina*, and *F. nilgerrensis* belong to the *F. vesca* group and so far have not appeared to have qualities of value for breeding. *F. daltoniana* is unproductive, since it has one-flowered flower clusters. The fruit of *F. collina* is very small, and the plants have not survived in Maryland. The berries of *F. nilgerrensis* are many-seeded and rather tasteless. The plant, however, is vigorous. A number of varieties of the everbearing *F. vesca* var. *semperflorens* are grown to some extent in Europe. Though the fruit is smaller than that of American cultivated sorts, it is aromatic and borne freely throughout the summer in the climatic conditions of northern Europe, but it has not been successful in the United States. The fruit of *F. vesca* and *F. californica* is small—too small to be worth while.

Varieties of *Fragaria moschata*, the open wood strawberry of Europe, which has 21 pairs of chromosomes, are cultivated to some extent in European gardens for their very aromatic vinous-flavored fruit. Though the fruit is small, it is larger than that of the alpines. Varieties like Royal Hautbois and Black Hautbois grow fairly well in the northern United States if protected in the winter, but they have never succeeded commercially. La Constante, a French variety supposedly derived from *F. chiloensis* × *virginiana*, is reported to have much of the vinous flavor of *F. moschata* and may possibly be a source of this flavor for breeders.

Species With 14 Pairs of Chromosomes

Species with 14 pairs of chromosomes have not been known in the wild until recently, when Fedorova (*27*) reported that Petroff found a form with 14 pairs of chromosomes, which he referred to as *Fragaria orientalis* A. Los. Los., an eastern Asiatic species formerly classified with botanical varieties of *F. vesca*. Longley has suggested that the ancestral strawberry from which the others descended was close to *F. vesca*. This has the basic number of 7 chromosomes in the germ cells (diploid number 14). Lilienfeld (*39, 40*) recently has apparently proved that *F. moschata* (*F. elatior*), which has 21 chromosomes in the germ cells (diploid number 42), actually was derived in ages past from species with 7 pairs of chromosomes. He reached this conclusion because, in crossing a species having 7 pairs of chromosomes with one having 21 pairs of chromosomes, 14 chromosomes of *F. moschata* paired with 14 from the *vesca* type, and 2 sets of 7 from *F. moschata* paired with 2 other sets just as though they were a 14-chromosome species. The resulting seedlings were fertile and constitute a new species with 14 pairs of chromosomes named by Lilienfeld *F. elnipponica* Lil. (derived from *F. elatior*, a synonym of *F. moschata*, and *F. nipponica* Mak., which is a Japanese form of

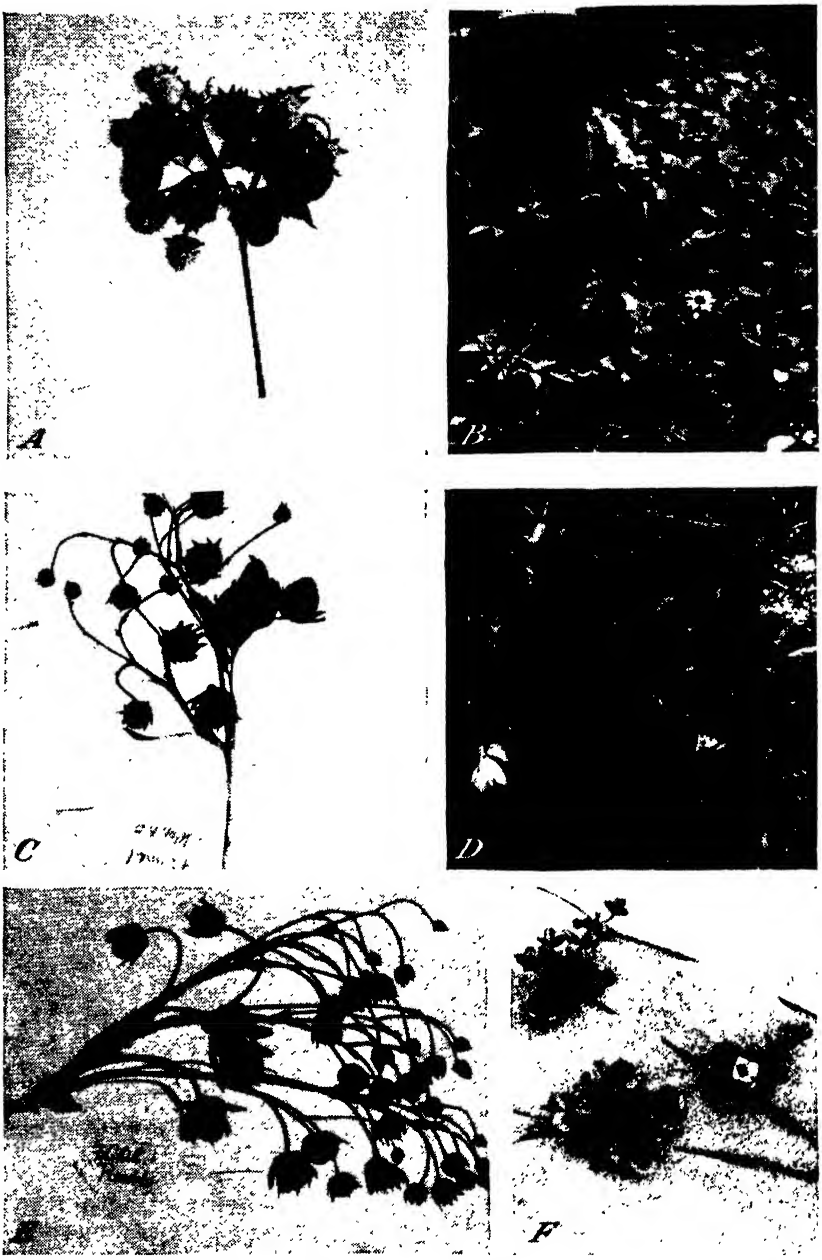

Figure 17.—Native American strawberry species: *A*, *B*, *Fragaria virginiana*, of eastern North America; *C*, *D*, *F. cuneifolia*, of western North America; *E*, *F*, *F. chiloensis*, of the beaches from Alaska to California and of Chile. These are the three 56-chromosome species, from two of which the cultivated strawberry has descended.

Figure 18.—European and Asiatic strawberry species: *A*, *B*, *Fragaria nilgerrensis*, a 14-chromosome strawberry of southern Asia; *C*, *D*, *F. vesca*, the 14-chromosome wood strawberry of Europe; *E*, *F*, *F. moschata*, the 42-chromosome open wood strawberry of Europe. *F. nilgerrensis* is a rather tasteless strawberry but may possibly be of use for breeding. From an everbearing form of *F. vesca* have originated the small alpine strawberries grown in the gardens of Europe. From *F. moschata* have come the high-flavored, rather small Hautbois varieties of Europe.

F. vesca). Yarnell also raised 14-chromosome seedlings from *F. bracteata* × *vesca* var. *rosea*, and Fedorova (*27*) 14-chromosome seedlings from *F. vesca* × *moschata*.

In a similar manner East (*26*) was able to get pairing of one set of chromosomes from *F. vesca* ($n=7$) with a set from *F. virginiana* ($n=28$). Though the resulting diploid seedlings were not as fertile as seedlings of *F. vesca*, the chromosomes were actually related closely enough to pair. Apparently through the ages since the 28-chromosome species originated, some changes have occurred in the chromosomes, but not enough to prevent pairing.

Species With 21 Pairs of Chromosomes

The only known species with 21 pairs of chromosomes is *Fragaria moschata*, which has been discussed above.

Species With 28 Pairs of Chromosomes

Fragaria virginiana, *F. cuneifolia*, and *F. chiloensis*, the group from which the cultivated strawberry has descended, each has 28 pairs of chromosomes. *F. cuneifolia* is the Rocky Mountain wild strawberry, native from Arizona to Alaska and Colorado to Oregon. It has been used very little in breeding. However, its resistance to low winter temperatures and drought and its everbearing character at low elevations indicate its potential value.

Many attempts have been made to cross *Fragaria vesca* and *moschata* with the cultivated strawberry. Such crosses have actually been made, but in carefully controlled tests the seedlings have been entirely or nearly sterile. However, evidence indicates that all four sets of chromosomes of the cultivated strawberry and of the species with 28 pairs of chromosomes had a common origin and are probably homologs of those of *F. vesca*. It seems entirely possible that in some cases where cultivated varieties have been crossed with varieties of *F. vesca*, true hybrid seedlings may have originated by a substitution of 7 chromosomes of *F. vesca* for a set of 7 of the mother plant, and, by a subsequent doubling of the 28, a seedling with the full 28 pairs developed. If the sets are homologs, as suggested by Longley (*41*) and East (*25*) and if those of *F. vesca* should pair with those of the cultivated strawberry, the differences in seedlings might be so slight as to be unnoticed. The everbearing crosses (Chesapeake × *F. vesca* and Early Jersey Giant × *F. vesca*) reported by Van Fleet may have had such an origin, for neither Chesapeake nor Early Giant seedlings would be expected to be everbearing.

Chromosomes of the Strawberry

Yarnell (*63*) studied the chromosomes of strawberries in an attempt to find constant differences among them and concluded that the only constant difference was in length. He found that their small size, their shape, and their position made even an estimate of length difficult. He found the chromosomes of different species very similar. The length averaged 1.7, 1.5, 1.4, 1.3, 1.2, 1.0, and 0.9 microns. The two shorter and the longest were usually easy to distinguish, but the others were not.

Longley (*41*), Yarnell, and Lilienfeld (*40*) all suggest that the chromosome sets in the species with 21 pairs and 28 pairs of chromosomes are homologs. Longley notes also that variability is associated with polyploidy and that the species with 7 pairs of chromosomes are much less variable than the species with 21 or 28 pairs of chromosomes. The diploid *Fragaria* are perfect-flowered, and sex differentiation occurs only in polyploid forms. So far as the wild forms are known, the species with 21 pairs and those with 28 pairs of chromosomes are far more variable than the forms with 7 pairs of chromosomes, and it is evident that variability has come in with polyploidy.

Hybrids Between Chromosome Groups

Millardet (*45*) in France, Richardson (*48, 49, 50, 51*) in England, Solms-Laubach (*56*) in Austria, and Schiemann (*54*) in Germany have made crosses between species of the different chromosome groups. However, the crosses made at the Bussey Institute by East and by two of his students, Mangelsdorf (*43, 44*) and Yarnell (*62, 63, 64, 65*), and reported by these investigators and by Ichijima (*33, 34*), cover most of the species crossed. An outline of the crosses reported by them follows:

Hybrids within the groups having 7 and 28 pairs of chromosomes [8]

Species with 7 pairs of chromosomes:

- *Fragaria californica* Cham. and Schlecht. × *bracteata* Heller (= *californica*), F_1 fully fertile.
- *F. californica* Cham. and Schlecht. × *vesca rosea* Rostr., F_1 fully fertile.
- *F. collina* Ehrh. (= *viridis*) × *maxima* (?), F_1 flowered.
- *F. collina* Ehrh. × *nilgerrensis* Schlecht., F_1 vigorous.
- *F. mexicana* Schlecht. (= *vesca*) × *americana alba* Clute (= *vesca alba* or *vesca americana alba*), F_1 fully fertile.
- *F. americana alba* Clute × *mexicana* Schlecht., F_1 fully fertile.
- *F. vesca rosea* Rostr. × *americana alba* Porter, F_1 fully fertile.
- *F. vesca rosea* Rostr. × *mexicana* Schlecht., F_1 fully fertile.
- *F. vesca rosea* Rostr. × *collina* Ehrh., F_1 partially fertile.
- *F. vesca* L. × *vesca rosea* Rostr., F_1 fully fertile.
- *F. vesca* L. × *nilgerrensis* Schlecht., F_1 dwarfs, no flowers.
- *F. vesca* L. × *americana alba* Porter, F_1 fully fertile.
- *F. vesca* L. × *maxima* (?) (= *vesca* or *vesca maxima*), F_1 partially fertile.
- *F. vesca* L. (Tiflis, Union of Soviet Socialist Republics) × *vesca rosea* Rostr., F_1 fully fertile.
- *F. bracteata* Heller × *vesca rosea* Rostr., F_1 flowered.
- *F. bracteata* Heller × *americana alba* Porter, F_1 fully fertile.
- *F. bracteata* Heller × *collina* Ehrh., F_1 partially fertile.
- *F. bracteata* Heller × *maxima* (?), F_1 partially fertile.
- *F. bracteata* Heller × *nilgerrensis* Schlecht., F_1 dwarfs, no flowers.

Species with 28 pairs of chromosomes:

- *F. chiloensis* Duch. × *virginiana* Duch., F_1 fully fertile.
- *F. virginiana* Duch. × *chiloensis* Duch., F_1 fully fertile.
- *F. virginiana* Duch. × *glauca* Rydb. (= *cuneifolia*), F_1 fully fertile.
- *F. chiloensis* Duch. × *platypetala* Rydb. (= *cuneifolia*), F_1 fully fertile.

Mangelsdorf and East reported on hybrids between different chromosome groups—14 × 42, 14 × 56, 56 × 42—and on generic crosses. *Fragaria vesca* ($2n=14$) × *elatior* (=*moschata*) ($2n=42$) resulted in no F_1 plant that fruited out of 600 seeds. *F. vesca* ($2n=14$) × *chiloensis* ($2n=56$) resulted in 6 nonblooming seedlings out of over

[8]The species names are those given by various authors, followed in some cases by identifications.

1,200 seeds. *F. americana alba* (=*F. vesca alba* or *F. vesca americana alba*) ($2n=14$) $\times$ *glauca* (=*F. cuneifolia*) ($2n=56$) gave only 1 plant from 66 seeds, and it did not bloom. *F. vesca* ($2n=14$) $\times$ *glauca* ($2n=56$) gave 5 nonfruiting plants out of 250 seeds. *F. vesca rosea* ($2n=14$) $\times$ *glauca* ($2n=56$) gave 7 nonfruiting plants from 76 seeds. *F. vesca* ($2n=14$) $\times$ *virginiana* ($2n=56$) gave 21 F_1 plants from 500 seeds, none of which was fertile. *F. bracteata* (=*F. californica*) ($2n=14$) $\times$ *virginiana* ($2n=56$) resulted in 10 nonfruiting plants from 24 seeds and 2 pistillate plants that crossed with *F. vesca rosea.*

F. virginiana ($2n=56$) $\times$ *elatior* ($2n=42$) resulted in 90 plants from 100 seeds, many of the plants being vigorous; all those considered hybrids were sterile.

Yarnell crossed chromosome groups as follows: 14×28, 14×42, 14×56, 42×28, 56×28, and 56×42. The 14×28, 14×42, and 42×28 proved to be nearly or completely sterile. The 56×28 cross gave flowering plants, but none produced pink flowers as would be expected with pink dominant. This is explained by assuming that the crosses were hexaploid $\frac{28 \times 14}{2}$ and that there were four recessive factors for color (*pppp*) and only two dominant factors (*PP*). In a seedling having the composition *PPpppp*, the two dominant genes would be unable to function.

Inheritance in the Species With Seven Pairs of Chromosomes

Richardson (*48*) in England obtained normal hybrid segregation in the species *Fragaria vesca*, with seven pairs of chromosomes. He crossed a trifoliate with a monofoliate plant. The F_1 plants were all trifoliate. When these were selfed he got 177 trifoliate to 73 monofoliate instead of the expected 187.5 to 62.5. He also crossed a white- with a red-fruited variety. The F_1 plants were red-fruited but when selfed gave 70 red-fruited to 20 white, which is close to the theoretical 67.5 to 22.5. In crosses between single- and double-flowered forms the F_1 was single but gave 155 single to 62 double in the F_2 instead of 163 single to 54 double. A cross between runnerless and runner-producing gave runner-producing in the F_1, but 342 runner-producing to 97 runnerless in the F_2 instead of the expected 329 runnered to 110 runnerless. Though the above four characters showed inheritance not far different from the expected 3 to 1 ratio, Richardson had difficulty in classifying his F_2 in a cross between pink- and white-flowered plants. Mangelsdorf and East, however, obtained 128 pink and 46 white in a similar cross, which is very close to the expected 3 to 1 ratio. They also crossed red- with white-fruited plants and obtained 102 red-fruited to 56 white-fruited plants instead of 118.5 red to 39.5 white.

Generic Crosses

Fragaria vesca ($n=7$) $\times$ *Duchesnea indica* (L.) Focke ($n=42$) resulted in 30 plants from 500 seeds, 26 being hybrids, all small and weak. *F. vesca* ($n=7$) $\times$ *Potentilla nepalensis* Hook. (n unknown) resulted in 2 seedlings from 141 seeds, but both died before flowering. Crosses between the strawberry and the raspberry have been reported, but the proof of such crosses has not been fully established. The so-called strawberry-raspberry is not a hybrid but a low-growing

raspberry from China; and the so-called tree strawberry is simply a species of tree, *Arbutus unedo* L., bearing fruit with a slight resemblance to a strawberry.

Unusual Inheritance in Fragaria

Paternal inheritance.—Millardet (*23, 24, 45*) reported four cases in which the seedlings resembled the male parent. These crosses were *Fragaria vesca* × Globe, *F. vesca* × Ananas, *F. vesca* × *chiloensis* ($n=7 \times n=28$ crosses), and *F. moschata* (*elatior*) × Globe ($n=21 \times n=28$). Though the first two crosses gave sterile seedlings and the last two gave seedlings with reduced fertility, they may have been physiological males or imperfect hermaphrodites. Ichijima (*33*), working at East's laboratory, counted chromosomes of several patroclinous hybrids and found them equal to the sum of the haploid numbers of the parents. In a cross of *F. vesca* (*rosea* × *alba*) × *virginiana*, however, Ichijima found one plant with a somatic number of 56 chromosomes that was close to *F. virginiana* in appearance. Yarnell has also reported two octoploid seedlings from crosses of $n=7 \times n=28$ plants. Longley also reported a cross of *F. vesca alba* × Aroma where the seedling resembled the male parent and had the same chromosome number. Rygg and Darrow (*53*) found a considerable percentage (1.2 percent) of such plants out of 3,519 crosses of cultivated varieties × *F. cuneifolia*, both with parents with 28 pairs of chromosomes. Waldo has also found 5 plants of the maternal, 22 of the paternal, and 6 of the hybrid types in a cross of *F. chiloensis* × *cuneifolia*. The full explanation of this appearance of seedlings identical with or very like the male is not yet apparent. However, an observation of Ichijima that the pollen mother cells have two nuclei, and observations by Rudloff (*52*) that two complete embryo sacs were often seen side by side in *F. virginiana* and *F. vesca* and that they may fuse, may have some bearing on this.

Pairing of chromosomes in an artificial polyploid.—When fertile tetraploids originated as the result of a cross of *Fragaria bracteata* (= *F. vesca californica*) × *vesca rosea*, Yarnell (*64*) concluded that the four homologous chromosomes paired at random. That is, the sets of seven chromosomes in each species were sufficiently alike so that the long chromosomes from *F. bracteata* might pair with the long ones from *F. vesca rosea*, and the short with short. However, a critical review of the *vesca* group indicates that *bracteata* might better be classed as a botanical variety, *F. vesca californica*, coordinate with *rosea*. If this classification be made, the chromosomes of this hybrid may be considered homologs of these botanical varieties of *vesca*.

Again in a cross of *Fragaria vesca alba* ($n=7$) × *virginiana* ($n=28$), East obtained a diploid hybrid. Nine of the F_2 were fertile, three seedlings did not flower for the 3 years they were observed, and seven were sterile. It is noteworthy that a set of seven chromosomes of *F. virginiana* paired with a set of *F. vesca alba* well enough to form some fertile seedlings. Yarnell also reported diploid hybrids of *F. vesca rosea* ($n=7$) × *glauca* (= *F. cuneifolia*) ($n=28$) and of *F. vesca alba* ($n=7$) × *chiloensis* ($n=28$).

Pairing of nonhomologous chromosomes.—Yarnell (*64*) reported that tetraploid plants resulting from crosses of *F. bracteata* × *vesca rosea* were

crossed with three species having seven chromosomes. The seedlings were triploids with 21 somatic chromosomes. Examination showed that the nonhomologous chromosomes paired. Later he reported other similar instances. Conditions were present—possibly high temperatures—that made possible the pairing of chromosomes that were not homologs, even though pairing of homologous chromosomes only is supposed to be essential to the Mendelian conception of heredity.

Production of homozygotes through induced parthenogenesis.—A single-factor pair, *Pp*, was found by East (*24*) and his students to be responsible for pink and white color of flower, and another pair, *Rr*, for red and white fruit color in the diploid species. In crossing *F. bracteata* × *vesca rosea*, a heterozygous red-fruited, pink-flowered plant was obtained. Among the diploid plants produced by crossing (*F. bracteata* × *vesca rosea*) × *virginiana* and × *chiloensis* there were 12 with red fruit and pink flowers, 3 with white fruit and pink flowers, 7 with red fruit and white flowers, and 2 with white fruit and white flowers. Some, or more probably all, of these diploids were considered to have arisen through induced parthenogenesis, that is, the embryo must have developed without fertilization. At the beginning of development, then, the organism was a haploid, but because the seedlings all proved to be diploids, the haploid chromosomes must have divided. Thus, the seedlings were homozygotes. East (*25*) points out that if a means can be found for inducing parthogenesis from which homozygous diploids develop, it might eliminate the uncertain and costly methods now employed to obtain plants that are homozygous.

Bud Selection in the Strawberry

Bud selection in the strawberry has never been a method of obtaining improved varieties or strains, as in apples, oranges, etc. Only a few kinds of bud sports have been observed. Only the probable production of an everbearing sport in the case of the Pan-American and of a noneverbearing sport in the case of the June Rockhill have had economic value. Another kind of sport—variegated foliage—is a serious limitation to the value of such varieties as the Blakemore, Howard 17, and many others.[9] Bud sports of many plants result in the appearance in somatic tissue of recessive characters. Thus, in the strawberry, selfed seedlings of varieties that sport to variegated plants show a proportion of yellow seedlings. If, as the evidence given above indicates is probable, most characteristics are quantitative, then a change in a single gene in one of the eight chromosomes is not likely to make enough of a change in the external appearance of the plant to be noted or measured.

TABLE 2. *Strawberry varieties originated by public agencies*

Location	Variety	Year introduced	Parentage	Superior qualities	Estimated acreage
UNITED STATES					
Federal station					
Beltsville, Md ...	Blakemore	1929	Missionary × Howard 17	Firm light red preserving southern	16 000
	Bellmar	1931	do	Attractive good flavor large	200
	Southland	1931	Ettersburg 80 × Howard 17	Attractive, high flavor in south, disease resistant	50
	Redheart	1931	Portia × Fairfax	Very firm canning resistant to crinkle	700
	Dorsett	1932	Howard 17 × Royal Sovereign	Vigor, high flavor, disease-resistant	4,000
	Narcissa	1932	do	do	100
	Fairfax	1932	Unknown	do	500
	Oxheart	1933	do	Firm, deep red, high flavor	None
State stations					
Alaska, Sitka	President Harding		Hollis × *Fragaria chiloensis*	Productive in Alaska firm high flavor	
Minnesota, Excelsior	Duluth	1923	Pan American × Dunlap	Productive, everbearer, hardy	Small
	Minnesota	1920	Dunlap × Pocomoke	Productive, attractive high flavor	Do
	Minnehaha	1920	Minnesota × Abington	Vigorous, hardy, large firm, late	Do
	Chaska	1922	(Dunlap × Pocomoke) × Brandywine	Attractive, high quality	Do.
	Easypicker	1922	Dunlap × unknown	do	Do
	Nokomis	1922	Dunlap × Abington	Productive, large	Do
	Deephaven	1922	Unknown	Everbearer	Do
New Jersey, New Brunswick	N. J. 35	1930		Attractive, productive	20
New York, Geneva	Hunn	1895	Johnson Late × Sharple	Late attractive	None
	Prolific	1908	Sample × Marshall	Very productive attractive	Do
	Magnus	1910	Hunn × Marshall	High flavor, large	Do
	Quality	1910	Hunn × Atlantic	High flavor, late	Do
	Addison	1918	President × Marshall	Productive, mild, large	Do
	Alden	1918	do	Productive, glossy, large	Do
	Angola	1918	do	do	Do
	Arcade	1918	do	Productive, firm, large	Do
	Argyle	1918	do	Productive glossy large	Do
	Ashton	1918	do	do	Do
	Athens	1918	do	Productive bright red large	Do
	Aurora	1918	Seedling of Prolific	Vigorous firm, large	Do
	Beacon	1923	President × Marshall	Early, large attractive	Small
	Bliss	1923	Chesapeake × Atkins	Late high flavor, attractive	Do
	Boquet	1923	Chesapeake × Pan American	Firm productive	Few acres
	Caledonia	1929	Marshall × Howard 17	Preserving	Small
	Camden	1931	do	Mild, productive, vigorous	Do
	Cato	1929	do	Vigor, high flavor	10
	Catskill	1933	do	Very large attractive productive	500
	Clermont	1929	do	Attractive holds up in size	100
	Culver	1931	do	Preserving, attractive	Small

TABLE 2.—*Strawberry varieties originated by public agencies*—Continued

Location	Variety	Year introduced	Parentage	Superior qualities	Estimated acreage
UNITED STATES—continued					
State stations—Continued.					
North Dakota, Fargo	Dry Weather	1925	Americus × Howard 17	Sweet, drought-resistant, everbearer	2.
Oregon, Corvallis	Corvallis	1930	Ettersburg 121 × Marshall	High flavor, fine texture, canner, freezing	150.
South Dakota, Brookings (51).	Dakota No. 1	1907	Jessie × Manitoba Wild	Possibly hardiest variety	Small.
	Dakota No. 2	1907	Glen Mary × Cavalier Wild	Hardy	None.
Tennessee, Knoxville	McClintock	1932	Aroma selfed	Large, productive	Small.
FOREIGN:					
Canada:					
Dominion Experimental Farm, Ottawa.	Bianca	1913			None.
	Cassandra	1913	Seedling of Bubach	Large, glossy, late, attractive	Some.
	Celia	1913			None.
	Cordelia	1913	Seedling of Bubach	Deep salmon color, productive	
	Desdemona	1913	do	Dark red, good flavor	Do.
	Francesca	1913			Do.
	Helana	1913			Do.
	Hermia	1913	Seedling of Wm. Belt	Firm, attractive	Do.
	Julia	1913	Seedling of Bubach		Do.
	Lavinia	1913			Do.
	Lucetta	1913	Seedling of Bubach	Firm, attractive	Do.
	Mariana	1913	do	Productive, attractive	Do.
	Miranda	1913		Large, glossy	Do.
	Octavia	1913			Do.
	Olivia	1913			Do.
	Ophelia	1913	Seedling of Wm. Belt	Large, bright scarlet	Do.
	Portia	1913	do	Firm, excellent canner	Some.
	Viola	1913	Seedling of Wm. Belt	Firm, large	Do.
	Virgilia	1913	do	Deep red, large	Do.
Alberta, Lacombe	Lacombe	1928	Late Stevens × Dunlap	Hardy, good preserver	
British Columbia, Sidney	New Victoria	1930	Royal Sovereign × Magoon	Large, firm, drought-resistant	
Ontario:					
Guelph	O. A. C	1925	Parsons × Howard 17	Large, glossy, red	
Vineland	Valentine	1919	Williams × Brandywine	Excellent flavor	None.
	Valet	1919	do	Large, similar to Joe	Do.
	Valiant	1919	Brandywine × Williams	Oval, smooth	Do.
	Valid	1919	Dunlap × Ozark	Large, dark, productive	Do.
	Valonic	1919	do	Light, bright color	Do.
	Valor	1919	do	Early	Do.
	Vambrace	1919	do		Do.

	Van Dyke	1919	do.	Early, productive	Some.
	Vanessa	1919	Dunlap × Brandywine	Large, home use	None.
	Vanguard	1919	Pocomoke × Ozark		Do.
	Vanilla	1919	Dunlap × Williams	Large, attractive	Do.
	Vanquish	1919	Dunlap × Pocomoke	Late	Do.
	Vantage	1919	Williams × Ozark	Large, firm, dark	Do.
	Vaquero	1919	Williams × Dunlap	Large	Do.
	Varangian	1919	do	Large, firm	Do.
	Vassal	1919	Ozark × Williams	Early	Do.
	Vast	1919	Ozark × Michel	do	Do.
	Vaunt	1919	Brandywine × Michel	do	Do.
	Vavasor	1919	Pocomoke × Ozark	Large	Do.
	Vaward	1919	do	Early	Do.
	Vector	1919	do	Large, bright	Do.
	Veda	1919	Sample × Dunlap	Very large	Do.
	Vena	1919	Parsons × Michel	White flesh	Do.
	Vendance	1919	Nettie × Williams	Very late, large	Do.
	Vendor	1919	Dunlap × Ozark	Large, very dark	Do.
	Vendue	1919	Williams × Ozark	High flavor, early	Do.
	Venus	1919	Joe × St. Louis	Large, very late	Do.
Manitoba, Morden	Rosthern	1929		Hardy, large, light color	Do.
Czechoslovakia, Pruhonice	Prof. Jelinck		M. Moutot × Deutsch Evern	Early, hardy	
	Bonmir Landovsky		Kentish Favorite × Deutsch Evern	Early, firm, large	
England:					
Merton, John Innes Horticultural Institution.	Richardsons Seedling			Sweet	
	Seedling D_1			do	
Germany, Pillnitz	Oberschlesien [1]	1924		Large, deep red, vigorous, productive	
	Johannes Muller				
	Frau M. Schindler				
	Pillnitz				
	Herbstfreude				
	Mathilde				
Sweden, Alnarp	Inga	1933	Frau Direktor Echtenmeyer × V. H. de Thury.	Early, excellent flavor	
	Stella	1933	do	do	
	Luna	1934	Late Leopold × V. H. de Thury	Early, excellent flavor, productive	

[1] Raised by Max Richter.

TABLE 3.—*Strawberry varieties originated by private breeders*

Name and address	Variety	Year introduced	Parentage	Superior qualities	Estimated acreage
C. H. Beaver, Eau Claire, Wis.	Beaver	1925	Howard 17 × Burrill	Hardy, productive, good shipper	2,000.
E. C. Howard, and father, A. B. Howard, Belchertown, Mass.	Dighton	1908		High flavor	
	Howard 17	1909	Crescent × Howard No. 1	Early, productive, large, attractive, frost and disease resistant.	32,000.
	Howard Supreme	1929	Howard 103 × Howard 17	Productive, high flavor, excellent for freezing	75.
J. E. Kuhns, Cliffwood, N. J.	Aberdeen	1923		Productive, resistant to brown stele disease	2,000.
George Voer, Peru, Ind.	Mastodon	1924	Kellogg Prize × Superb	Productive, everbearing, produces runners freely	1,000.
Keith Bros., Sawyer, Mich.	Kanner King	1932		Dark red, firm, canner	Small.
	Joan	1933	Ananas de Guemene × Mastodon	Large, everbearing	
	Uncle Cap	1933	Mastodon seedling	Large, sweet, everbearing	
H. Rockhill, Conrad, Iowa	Francis	1910	Louis Gautier × Pan American	Very good flavor, everbearing, early	None.
	Americus	1911	do	Excellent flavor, everbearing	Do.
	Iowa	1911	Dunlap × Pan American	Everbearing	Do.
	Progressive	1911	Pan American × Dunlap	Everbearing, vigorous, very hardy, excellent flavor, early, healthy.	200.
	Standpat	1914	do	Everbearing, large	None.
	Rockhill (Wazata)	1922	Progressive × Early Jersey Giant	Everbearing, large, one of best flavored berries in United States, large, disease-resistant, very hardy.	200.
	June Rockhill	1932	Rockhill sport	Noneverbearing, but like Rockhill otherwise	Small.
Gardner Nurseries, Osage, Iowa	Red Gold	1925	Howard 17 × Everbearer	Sweet, large	
	Gardner 1000	1918		Everbearing, propagates freely	
	Gardner 999	1925		Everbearing, high flavor	
W. Kosuga, Sandy, Utah	Berri Supreme	1929		Everbearing	20.
	Twentieth Century	1936	Berri Supreme × Rockhill	do	
A. F. Etter, Ettersburg, Calif.	Rose Ettersburg	1903	(Sharpless × Parry) F_2 × *Fragaria chiloensis*, Peru.	Vigorous, productive, fragrant, drought-resistant	None.
	Ettersburg 121	1907	Derived from *F. chiloensis* × ?	Vigorous, many crowns, hardy foliage, best canner in United States, solid, high flavor, very late.	250.
	Ettersburg 80	1912	In part at least from Rose Ettersburg and a selection of *F. chiloensis*	Vigorous, large, healthy foliage, solid flesh, large	Little in the United States, but some in Australasia.
	Nor-J	1913	Fendall × Ettersburg 121	Productive, firm	None.
	Ettersburg 76	1913	(Michel[1] × Rose Ettersburg) × *F. chiloensis*.		Do.
	Ettersburg 84	1913	Sister to Ettersburg 80.	Vigorous	Do.
	Ettersburg 86			Firm, pale	Do.
	Ettersburg 89	1913	Dornan and *F. chiloensis*	Vigorous, few runners	Do.
	Ettersburg 111	1913	Sister to Ettersburg 80	Productive, drought-resistant	Do.
	Ettersburg 112	1913	do	Large, glossy	Do.

Ettersburg 91	1914	do	Deep red, high flavor, drought-resistant	Do
Ettersburg 71	1914		Cap or calyx stays on plant, light pink	Do
Ettersburg 75	1914	(Michel [1] × Rose Ettersburg) × *F chiloensis*	Red to center, firm	Do.
Ettersburg 79	1914	do	Deep red, high flavor	Do
Ettersburg 88	1911	Wm Belt cross	Deep red, canning variety	Do
Ettersburg 93	1914	Sister to Ettersburg 80	Deep, glossy red	Do
Ettersburg 94	1914	Rose Ettersburg × *F chiloensis*	Very attractive, acid	Do
Ettersburg 106	1914	do	Vigorous, pink, evergreen	Do
Ettersburg 114	1914	Rose Ettersburg × Michel [1] × –	Similar to Ettersburg 94	Do
Ettersburg 116	1914	Sister of Ettersburg 91	do	Do
Ettersburg 200	1914	Dunlap × *F chiloensis*, Peru	Pink, productive, deep-set seeds	Do
Ettersburg 330		Ettersburg 24 (Michel × Rose Ettersburg) cross	--	Do.
Ettersburg 450	1920	- ---	Excellent flavor, large, firm, attractive	Do
Ettersburg 904			Sweet, very firm	Do
Euresko (Eurisko)	1916	Chesapeake × Ettersburg 20 (Rose Ettersburg × *F chiloensis*)	Deep red to center, firm	Do
Beaderarena	1916	*F chiloensis* × Bederwood	Very hardy foliage, attractive	Do
Califour	1918	Ettersburg 88 × 2	Deep red, black raspberry flavor	Do
Delecto	1918		Juicy, high flavor, late	Do
Fendalemo	1918		Deep red, vigorous	Do
Beaderarena, Jr		Seedling of Beaderarena	High flavor, sweet .	Do
Fantastic	1918	Fendall × Ettersburg 121	Vigorous large	Do
Ossie	1918	Seedling of Ettersburg 81	Meaty flesh, early, showy	Do
Cream	1920	Ettersburg 330 × Trebla	Yellow cream color, productive, late	Do
Fendalcino	1920	Fendall × Ettersburg 121	Large, resistant to heat, productive	Do
Kalicene	1920	Ettersburg 216 × Trebla or Ettersburg 121 × Trebla	Early, solid flesh, very productive red center, vigorous	Do
Lnge	1920	Unknown	Canning, solid, brilliant red, firm	Do
Red Cross	1920	Ettersburg 216 × Trebla	Very glossy, sweet, attractive, uniform shape	Do
Rena	1920	Probably *F chiloensis* × Ettersburg 84	Light pink, similar to *F chiloensis*, late	Do
Trebla	1916	Ettersburg 114 × Ettersburg 84	Firm, solid, productive, frost resistant	Small
White Sugar	1920	Unknown	White to pink, sweet, firm, large, late	None
Red Sugar		Cross of Ettersburg 80		Do
Late Cross		Seedling of Red Cross	Late, resembles Ettersburg 80	Do
Redfour		Ettersburg 121 × Trebla	Large, canner, early	Do
Von Humboldt	1930	(Rose Ettersburg × *F chiloensis*) × cross of similar parentage	Evergreen, heavy foliage, vigorous	
Alcatraz		Red Sugar × Kalicene	Meaty	
Wickson	1930	(Red Sugar × Ettersburg 121) × *F cuneifolia*	Evergreen, heavy foliage, firm	
Golden Gate		Red Sugar × Kalicene	Firm, high flavor, large	
Elinor	1933		Pink	
Hard	1933		Firm, meaty	
Kandykid			Deep red, firm canning	
New Deal	1935	Probably Red Sugar × Ettersburg 121 or Trebla		--
Gracilis	1935	*F chiloensis* hybrid	. .	--

[1] Not true Michel, as Mr Etter reports it as pistillate while Michel is perfect flowered

TABLE 3.—*Strawberry varieties originated by private breeders*—Continued

Name and address	Variety	Year introduced	Parentage	Superior qualities	Estimated acreage
Thomas Laxton, Bedford, England.	Traveller	1872	La Constante × Napier	Deep scarlet	
	Exquisite	1874			
	Pioneer	1876		Large, attractive	
	Noble	1884	Seedling of Sharpless	Large, attractive, productive, wide adaptation	
	Captain	1884	Crown Prince × Foreman Excelsior	Most attractive of all, early	
	A. F. Barron	1885	Sir J. Paxton × Sir C. Napier	Glossy, scarlet	
	Jubilee	1887		Late	
	King of the Earlies	1888	Vicomtesse × Black Prince	Very early, high flavor	
	Commander	1889	British Queen × President	High flavor	
	Competitor	1890	Kerr Prolific × Foreman Excelsior		
	Scarlet Queen	1891	King of the Earlies × Noble	Early, attractive, high flavor	
	White Knight	1891	King of the Earlies × Noble	Light scarlet × white	
	Royal Sovereign	1892	Noble × King of the Earlies	Large, bright, scarlet, firm, high flavor	
	Latest of All	1894	British Queen × Helena Gloede	Late, very large, crimson, productive	
	Monarch	1895	Latest of All × Captain	Large, attractive	
	Leader	1895	Latest of All × Noble	Large, deep crimson, sweet	
	Laxton No. 1		Noble × May Queen	Earliest	
	Bedford Champion	1895	Seedling (Scarlet Queen × John Ruskin) × seedling (Noble × Sir J. Paxton.)	Very large, scarlet, sweet	
	Mentmore	1897	Noble × British Queen	Crimson	
	Fillbasket	1897	Royal Sovereign × Latest of All	Scarlet, productive	
	Reward	1898	Royal Sovereign × British Queen	Large, high flavor, attractive	
	Trafalgar	1900	Latest of All × ?	Late, large, attractive	
	Climax	1901	Latest of All × Waterloo	High flavor, large, firm	
	The Laxton	1901	Royal Sovereign × Sir J. Paxton	Large, firm, vigorous	
	The Bedford		Dr. Hogg × Napier	High flavor, scarlet	
	Latest	1904	Latest of All × seedling	Very large, week later than Waterloo	
	Progress	1906	British Queen × Latest of All	Late, bright scarlet, large	
	Cropper	1907	Seedling × Fillbasket	Productive, large, crimson	
	Reliance	1907	V. H. de Thury × seedling of St. Joseph.	Productive, scarlet	
	Perpetual	1907	Monarch × St. Joseph	Large, sweet	
	Profit	1908	Sir J. Paxton × Countess	Firm, productive, deep scarlet	
	Rival	1909	Givons Late × Royal Sovereign	High flavor, late, deep scarlet	
	Utility	1909	Seedling 500 × Waterloo	Firm, high flavor	
	Connoisseur	1909	Scarlet Queen × Fillbasket	Excellent flavor, bright scarlet	
	Epicure	1909	British Queen × Fillbasket	Excellent flavor	
	Pine Apple	1909		Excellent flavor, bright scarlet	
	Unique			Crimson	
	The Count			do	
	Maincrop	1910	Bedford Champion × The Laxton	High flavor, large	
	The Earl	1911	Waterloo × Royal Sovereign	Preserving	

The Admiral	1914	Seedling × Bedford Champion	High flavor, productive, large
White Perpetual	1916	Louis Gauthier × St Antoine	Nearly white, everbearing
Everbearing	1916	-	High flavor
International	1916	Latest of All × seedling	Bright scarlet, firm, high flavor
King George V	1916	Royal Sovereign × Louis Gauthier	Bright scarlet, forcing, early
The Duke	1916	Seedling × Bedford Champion	Early, high flavor, scarlet, forcing
Tit Bit	1918	Reliance × Bedford Champion	High flavor, scarlet
Victory	1919	Seedling × British Queen	Crimson, sweet
Sir Douglas Haig	1919	Seedling × Dr Hogg	Scarlet, yellow seeds, sweet
Marshal Foch	1920	The Bedford × Sir Joseph Paxton	Firm, dark
Lord Beatty	1920	Seedling × Bedford Champion	Light red
Laxtonian	1921?	Seedling × seedling	High flavor, glossy, crimson, firm, large
Bountiful	1921	D × D	Scarlet, large
Abundance	1922	Fillbasket × The Earl	High flavor, large, sweet
Omega	1923	Seedling × Bedford Champion	Latest, sweet, scarlet, firm
Majestic	1924	Seedling × International	Bright, crimson, sweet, firm
Rearguard	1925	Latest × Omega	Late, sweet, productive
Robust	1925	Bedford Champion × Bedford	Crimson, sweet
Empress	1925	Seedling × seedling	Firm, preserving
Prolific	1926	do	Scarlet, sweet, resists mildew
Duchess of York	1927	Laxtonian × Duke	Bright scarlet, drought resistant
Primate	1928	Seedling × seedling	Firm, sweet, bright crimson
Acquisition	1929	do	Vigorous, disease resistant
The Queen	1929	Waterloo × Queen of Denmark	High flavor, pale scarlet

Sources of Superior Qualities in Strawberries

Note.—Though the following varieties and species are notable for superior qualities, it may be that they will not prove to be equally good transmitters of these qualities.

Plant characteristics:

Hardy against cold: *Fragaria cuneifolia* selections and crosses (Beltsville, Md., Corvallis, Oreg., Fairbanks, Alaska, and Cheyenne, Wyo.); *F. virginiana* selections (Fargo, N. Dak), Dakota, Dry Weather, Dunlap, Rockhill, Progressive, Parsons (Gibson), Beaver, Camden, Culver, Minnehaha.

Resistant to frost: Howard 17 and Chesapeake in United States, Sir Joseph Paxton in England.

Resistant to verticillium wilt: Chilean (*F. chiloensis*).

Resistant to brown stele (*Phytophthora*): Aberdeen, Mastodon, and Redheart in Illinois; Leopold and Oberschlesien in Scotland.

Resistant to leaf scorch: Southland, Fairfax, Howard 17, Dorsett. U. S. D. A. 1142 (652 × Ettersburg 450), 1572 (Howard 17 × Dorsett), 2124 (Chesapeake × Fairfax).

Resistant to leaf spot: Southland, Fairfax, Howard 17, Rockhill, U. S. D. A. 1142 (652 × Ettersburg 450), U. S. D. A. 2120 (Chesapeake × Fairfax), U. S. D. A. 2124 (Chesapeake × Fairfax).

Resistant to mildew: Marshall and Rockhill in the United States; V. H. de Thury (Stirling Castle), McMahon, and Aberdeen Favorite in England.

Resistant to aphid: Late Leopold, Bedford Champion, Aberdeen Standard, John Ruskin, Marshal Foch, and Sturton Cross in England.

Resistant to mite: Marshall in California; Mme. Kooi, Laxtonian, and Oberschlesien in England.

Resistant to crinkle: Redheart, Rockhill, and some *F. chiloensis* hybrids in Oregon.

Resistant to yellows (xanthosis): Nick Ohmer, Bellmar, and probably some *F. chiloensis* hybrids in California.

Resistant to heat: Missionary, Klondike, Blakemore, Southland, U. S. D. A. 1142 (652 × Ettersburg 450).

Resistant to drought: *F. cuneifolia*, U. S. D. A. 1791 (Ettersburg 904 × Howard 17), Marshall, Gold Dollar; The Duke and Waterloo in England.

Greenhouse forcing: Marshall in the United States; Royal Sovereign in Europe; Deutsch Evern in frames in the Netherlands; Noble in low houses in Germany.

Adapted to short days: Missionary, Klondike, Blakemore in the United States; Chilean in Ecuador.

Fruit characteristics:

Early ripening: U. S. D. A. 2267 (Missionary × Fairfax), U. S. D. A. 1631 (Howard 17 × Dorsett), Michel, Blakemore, Dorsett, Howard 17, Ozark, Progressive, Rockhill, Beaver, Early Bird, Minn. 1200; Deutsch Evern, Avant Tout, Laxton No. 1, and The Duke in England; Sir John Ruskin in Scotland.

Late ripening: U. S. D. A. 2263 (Ettersburg 904 × Fairfax), U. S. D. A. 2124 (Chesapeake × Fairfax), *F. chiloensis* and its crosses (Corvallis, Oreg., and New Brunswick, N. J.), Ettersburg 121, Wyona, Pearl, and Gandy. Omega, Latest, Utility, Jucunda, Rearguard, Givons, Waterloo, and Leopold in England.

Firm: U. S. D. A. 2166 (Joe × Redheart), U. S. D. A. 2120 (Chesapeake × Fairfax), Redheart, Fairfax, Blakemore, Minnehaha, U. S. D. A. 2161 (Joe × Redheart). Many Chesapeake × Fairfax and Blakemore × Fairfax selections have firm fruit.

Large: U. S. D. A. 2132 (652 × Fairfax), N. C. 337 (Bellmar × Fairfax), Catskill, Dorsett, Marshall, Minnehaha, Minn. 1201 (Marshall selfed). Latest and Laxtonian in Europe.

Yellow seeds: Blakemore, Chesapeake, U. S. D. A. 2061 (652 × Ettersburg 450), U. S. D. A. 1591 (Howard 17 × Dorsett), U S D. A. 2126 (Chesapeake × Fairfax).

Light scarlet color: Blakemore in United States; Royal Sovereign, Fillbasket, The Duke, The Queen, King George V in England.

Superior qualities for freezing: Fruitland, Joe, Big Late, Klondike in eastern United States; Howard Supreme in Massachusetts; Corvallis, Redheart (sliced), Marshall in Oregon and Washington. Also, selections from Blakemore × Ettersburg 450, Southland × Blakemore, Blakemore × Marshall, Blakemore × Klon-

dike, Redheart × Ettersburg 121, Blakemore × Ettersburg 121, Ettersburg 121 × Clark, Clark × Narcissa, and Howard 17 × Marshall in Oregon.

Superior qualities for preserving: Blakemore in United States; V. H. de Thury and Deutsch Evern in Europe. Reported good in some localities: Culver and Dorsett in United States; Lacombe in Canada. Marshall and Missionary are extensively used for preserving, though they are not equal to Blakemore. Crosses of Blakemore with other varieties have proved superior for preserving.

Superior qualities for canning: Redheart, Corvallis, Ettersburg 121 in the West; Portia in the East. Reported good in some localities: Culver, Redfour, Lnge, Trebla. Probably Noble, Scarlet Queen, and Paxton in parts of northern Europe. Crosses of Narcissa × Ettersburg 121, Redheart × Ettersburg 121, and Oregon 14 (Ettersburg 121 × Marshall) × Narcissa have produced good canning selections in Oregon.

Excellent flavor: Dorsett, Fairfax, Rockhill, Southland, Marshall, Corvallis, U. S. D. A. 1008 (*F. chiloensis* × Progressive), U. S. D. A. 1128 (Howard 17 × Ettersburg 450), U. S. D. A. 2183 (Missionary × Howard 17). British Queen, Dr. Hogg, Scarlet Queen, Connoisseur, Epicure, Pineapple, The Duke, Aberdeen Standard, and Royal Sovereign in Europe.

Unusual flavors: U. S. D. A. 1021 (Kalicene × Howard 17), grape flavor; U. S. D. A. 1026 and 1028 (Howard 17 × Ettersburg 450), apricot flavor; U. S. D. A. 1145 (652 × Ettersburg 450), raspberry flavor; Califour, black-raspberry flavor.

BLACKBERRY AND RASPBERRY IMPROVEMENT

GEORGE M. DARROW, Senior Pomologist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry [1]

BLACKBERRIES, INCLUDING DEWBERRIES

EXCEPT for the Logan (Loganberry), cultivation of the blackberry is chiefly limited to North America and most varieties of blackberries have originated in this country. Hedrick (*31*) [2] states that the blackberry came into cultivation little by little early in the nineteenth century. It became more common as a cultivated fruit about 1850, when several selections from the wild were introduced into cultivation. Among these was the Lawton, which is still grown. The Snyder variety was introduced about 1860, the Eldorado before 1891, and the Lucretia trailing blackberry or dewberry about 1875. These, as well as almost all others that have been grown commercially, were selections from the wild. Wilson Junior, raised from seed of Wilson Early, and Minnewaski, grown from seed at Marlboro, N. Y., have resulted from efforts to improve this fruit in Eastern States, but neither variety is now grown commercially to any extent.

In the West, efforts to improve the blackberry have met with much greater success. Selections of the wild trailing blackberry were first grown. Among these was the Aughinbaugh. In 1881, J. H. Logan raised the Logan and probably the Mammoth from seed of the Aughinbaugh. A second generation was raised from some of the seedlings, and from these the Black Logan and other promising varieties were selected. The Logan is still important, but the Mammoth is only occasionally grown now. The Black Logan may possibly still be raised, either as Black Logan or under other names. In 1897 Luther Burbank introduced the Phenomenal, very similar to the Logan. This was widely grown for a while, but it has largely disappeared.

About 1926 the Young dewberry (Youngberry) or trailing blackberry was introduced. This is a hybrid between the Phenomenal and the eastern Mayes dewberry (Austin Mayes), made by B. M. Young, of Louisiana. In 1935 the Boysen (Boysenberry), very similar to the Young, was introduced. Its origin is unknown.

In Oregon, Washington, and New Jersey the Evergreen or Black Diamond is cultivated. It is a very old variety from England that has

[1] Many experiment station workers and private breeders have contributed records and information. To these the writer is most grateful. Among those especially generous of their time were George L. Slate and L. M. Cooley (New York), J. H. Clark (New Jersey), A. S. Colby (Illinois), E. Angelo and A. N. Wilcox (Minnesota), C. F. Williams (North Carolina), and George F. Waldo (Oregon). W. J. Strong, M. B. Davis, N. H. Grubb. C. G. Dahl, and P. Stedje contributed information on work at foreign stations. B. M. Young (Louisiana), H. Rockhill (Iowa), W. E. Lammertz (California), and George Pyne, of Topham, Devon, England, have all contributed information.

[2] Italic numbers in parentheses refer to Literature Cited, p. 523.

become widely naturalized west of the Cascade Mountains in Oregon and Washington. In California, and to a slight extent in Oregon and Washington, the Himalaya (*Rubus procerus* P. J. Muell.) is raised. This is considered identical with the Theodor Reimers variety of Germany. It also is widely naturalized west of the Cascade Mountains Besides these two, several other European varieties that have been named in recent years have been tested, but no others have succeeded in the United States. In 1932 the Brainerd, a hybrid between the Himalaya and an eastern variety, was introduced. Thus, except for the Logan, Phenomenal, Young, Brainerd, and possibly the Boysen, the cultivated varieties of blackberries have originated as chance seedlings in the wild.

At present the Eldorado (Stuart) is the leading blackberry of the eastern erect type, Lucretia the leading trailing blackberry or dewberry of the eastern group, Logan and Young the leading trailing varieties of the western type. The Evergreen (Black Diamond) is the leading variety of the European type.

American Wild Blackberries and How Varieties Originated From Them

The wild blackberries of North America fall into five major groups: (1) The erect or nearly erect types, like Early Harvest (fig. 1) and Eldorado, of the eastern United States from Florida to Canada and from the Atlantic coast to the Prairie States; (2) the eastern trailing blackberries, not red-hairy caned, much like the Lucretia, having about the same range as the erect ones; (3) the southeastern trailing blackberries having red hairs on the canes, like the Manatee and Advance, ranging along the Atlantic and Gulf coasts from Delaware to Texas; (4) the trailing blackberries, from which the Logan is derived, of the Pacific coast from Canada to southern California; and (5) the semitrailing Evergreen (Black Diamond) and Himalaya

IN SPITE *of the fact that a good deal has already been accomplished, the possibilities of improving the red raspberry by utilizing the available cultivated varieties in further breeding work are still enormous. Some of the qualities, now found separately, that may be combined in raspberries of the future are the very large fruit size of European varieties and newer American productions, immense fruit clusters, great productiveness, firmness, vigor, and resistance to diseases. But there is also a large reservoir of germ plasm, hardly yet touched by raspberry breeders, in the wild species of Asia and elsewhere, some of which resemble the grape, hawthorn, bamboo, maple, and apple in their leaf forms, and vary from low and soft-stemmed plants to plants with stems 3 inches thick and 14 feet high.*

of Oregon, Washington, and California, that have been naturalized from Europe and which have become serious weeds of roadsides, pastures, and open forests. There are no native blackberries in the Rocky Mountains of the United States.

Originally, when North America was settled, most of the wild blackberries could be classified into a few relatively distinct species, and though blackberries were gathered from the wild, they were nowhere as abundant as at present. When the forests were cut and the land was cleared for pasture and meadow, the chief cover in many northern sections for several years was the wild blackberry. Birds ate the berries and dropped the seeds in the brush. These clearings of forest and pasture gave the opportunity for seedlings of different wild species to grow side by side, as they had not when dense virgin forest covered the land.

Figure 1.—**Early Harvest, derived from the eastern erect blackberry.**

Normally, the wild blackberries of the East are entirely or nearly self-sterile, and those of the Pacific coast have male and female organs on separate plants. All need cross-pollination. In the clearings and pastures bees and other insects have crossed the blackberry species for the last 100 to 300 years, and hybrid seedlings have grown up, so that immense numbers of hybrids may now be found. These hybrids vary from sterile to productive plants, and many are extremely vigorous. Backcrosses between a hybrid and one parent and crosses between hybrids are also appearing. Thus man, by clearing the forest, has started an immense breeding project. For the last 75 or 80 years man has been cashing in on this project by selecting the best of these wild hybrids and trying them under cultivation. Always he has overlooked the fact that the wild species were cross-fertilized.

Two or more selections were not planted together, so that many of the selections, when propagated by themselves under cultivation, were not productive. Furthermore, most of the wild blackberries are woodland plants, fruiting best in the leafmold at the edge of the forest and along streams. No wonder many of the selections were unproductive under cultivation. Through scores of years, however, selections of species and of hybrids have been found that have been productive when grown by themselves in open fields. In the South no productive selection that will set fruit by itself has yet been made of the trailing species with red-hairy canes. When the Rogers or Advance is grown, two or more selections are actually interplanted and cross-pollination is thus made possible, but many growers are unaware of this fact.

There is no final agreement as to just how many botanical species should be recognized, because the species have hybridized freely. Brainerd and Peitersen (*6*) list eight erect or semierect and four trailing species for New England. Canes of these species are shown in figure 2. Their survey of the wild forms was extensive and thorough and was supplemented by experiments on the effect of environment on botanical characters and by studies in hybridization. It seems best to follow their classification and viewpoint. The qualities of possible value to breeders are briefly described for several species as follows:

The "high-bush" or "black-long berry", *Rubus allegheniensis* Porter.—Canes strong, erect growing, with stout prickles; leaves mostly very large and strongly heart-shaped; clusters largest of American blackberries, 14- to 18-flowered; fruit large, long, sweet, and one of the best. Common in fields and pastures from New England to Wisconsin, but ranging from Minnesota to Nova Scotia and in the mountains to North Carolina and Tennessee. This is one of the purest and most distinct of northeastern erect blackberries. Snyder, though probably a hybrid, is close to the wild type, while Ancient Briton, Eldorado, Taylor, Agawam, Jumbo, Lawton, Stone, and Wachusett are probably hybrids of this species with others. Albino forms are fairly common in the wild.

The "tall" blackberry, *Rubus argutus* Link.—Canes very erect, deeply furrowed, prickly; clusters 8- to 12-flowered; fruit often with bitter aftertaste. This, or closely related forms, is the most common blackberry of the roadside and fields of the eastern United States. Early Harvest is close to the wild type of this species, while Erie is probably a hybrid.

The "short" or "square-fruited" blackberry, *Rubus pergratus* Blanch.—Canes tall and arching, prickly; leaves large and broad; clusters 8- to 12-flowered; fruit short, cylindric. A hardy blackberry of the higher elevations in New England, New York, and Pennsylvania, with large but short fruit of excellent flavor. It does not seem to be represented in cultivated varieties.

The "leafy-flowered" blackberry, *Rubus frondosus* Bigel.—Canes arched and recurving, prickly; leaves broad; clusters 8- to 12-flowered; fruit not so large as that of the above species. This is the common blackberry of the fields of New England, and next to *R. argutus* the most common of the blackberries of the eastern United States. It seems to thrive better than most species in the open fields. It has probably hybridized most extensively with *R. argutus*. Varieties nearest to the wild types are Joy, La Grange, Ward, and Watt, while most of the varieties listed above as hybrids of *R. allegheniensis* are probably hybrids with this species.

The "thornless mountain" blackberry, *Rubus canadensis* L.—Canes erect to arching, without prickles; leaves without hairs; leaflets long with long stalks, especially the terminal one; clusters loose; fruit long, tart. This thornless or prickleless blackberry is native to the higher mountains from Georgia northward to Newfoundland and Quebec, but is found at the lower elevations from northern Maine west to Wisconsin. It is a forest plant and does not succeed well at the lower elevations in open fields. Its fruit is excellent and the plant is very hardy northward. No variety derived from this is now under cultivation.

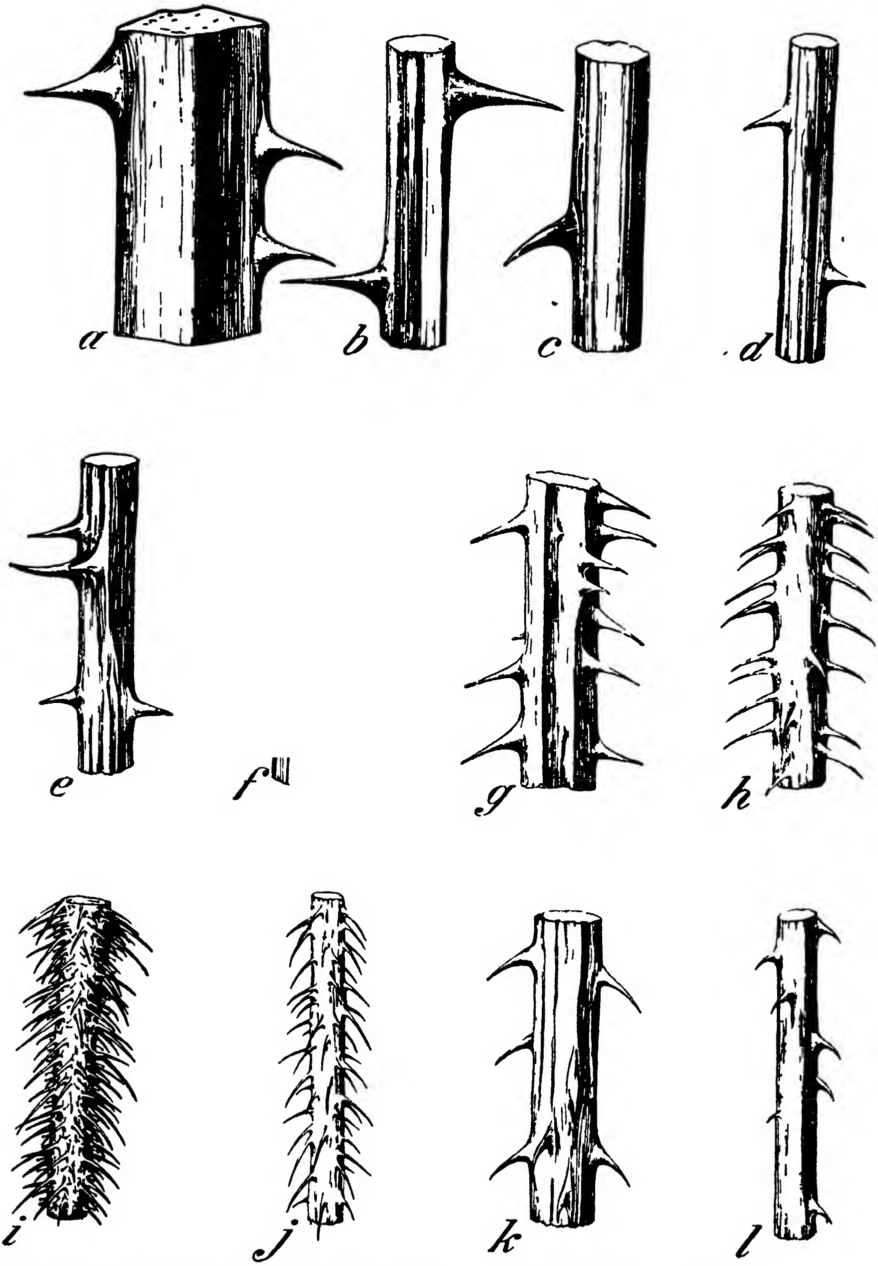

Figure 2.—Canes and prickles of 12 eastern species of the blackberry group (*Eubatus* section of genus *Rubus*): *a*, *Rubus allegheniensis*; *b*, *R. argutus*; *c*, *R. pergratus*; *d*, *R frondosus*; *e*, *R. recurvans*; *f*, *R. canadensis*; *g*, *R. elegantulus*; *h*, *R. vermontanus*; *i*, *R. setosus*; *j*, *R. hispidus*; *k*, *R. procumbens*; *l*, *R. baileyanus*. (After Brainerd.)

The "Vermont" blackberry, *Rubus vermontanus* Blanch.—A rather rare blackberry with recurving canes that has small but very numerous fruits. It is found at the higher elevations from New York to Nova Scotia and is quite hardy.

The "sand" blackberry, *Rubus cuneifolius* Pursh, is native along the coast from Connecticut to Texas and is not fully hardy in the North. It has very erect and quite thorny canes, and the fruit ripens much later than that of other American blackberries. In fact this species, with its often pink flowers, grayish foliage, and late fruit, is the closest of any to the European group of blackberries. Eureka belongs to this species, and Nanticoke is close to it.

The dewberry or trailing blackberry, *Rubus baileyanus* Britt.—Canes trailing, prickly; clusters one- to three-flowered; seeds large. This is one of the probable parents of the cultivated dewberries Mayes and Lucretia, which are probably hybrids of *R. baileyanus* with *R. argutus*. It is one of about three widely distributed trailing species in the eastern United States.

The "southern red-caned" dewberry, *Rubus trivialis* Michx.—Canes trailing, prickly, usually with dense red bristles, often evergreen; flowers large, usually solitary; fruit large, long, very early. This species, like the sand blackberry, is native along the coast from Maryland to Texas, but extends up the Mississippi Valley to Arkansas and southern Missouri. It has large, long fruit that ripens earliest of all. The Advance, Rogers, and Manatee all belong to this species. The Advance and Rogers have extremely firm fruit in several-fruited clusters and are apparently immune to double-blossom or rosette disease.[3] The limitations of the species are usually 1-flowered clusters, entire self-sterility (*24*), lack of hardiness except in the South, and prevalence of the double-blossom or rosette disease in the South.

The trailing blackberries or dewberries of the Pacific coast, *Rubus ursinus* Cham. and Schlecht., *R. macropetalus* Dougl., and *R. loganobaccus* Bailey.—Canes trailing, prickly, nearly evergreen; clusters usually 5- to 10-flowered, with sexes on separate plants; fruit to 1½ inches in length, deep wine colored to black. All three species are very subject to leaf spot and anthracnose, which limit their culture in the Eastern States. *R. macropetalus* occurs mostly in Oregon, Washington, and British Columbia, and *R. ursinus* and *R. loganobaccus* in California. All have highly flavored tart berries, the Logan being derived from *R. loganobaccus*, which occurs from about Watsonville north to the California-Oregon State line. The Young, Boysen, and Cameron derive their fine flavor from this latter species. Cazadero and other varieties have been derived from *R. macropetalus*.

The probable derivations of cultivated varieties are:

Rubus allegheniensis × *argutus:* Ancient Briton, Eldorado, Taylor.
R. allegheniensis × *frondosus:* Agawam, Erskine Park, Jumbo, Lawton, Snyder, Stone, Wachusett.
R. argutus × *frondosus:* Blowers, Erie, Mersereau.
R. baileyanus × *enslenii* Tratt.: Premo.
R. baileyanus × *argutus:* Mayes, Lucretia.
R. argutus: Early Harvest.
R. frondosus, or (*R. frondosus* × *argutus*) × *R. frondosus*· Joy, La Grange, Ward, Watt.
R. cuneifolius: Eureka, Nanticoke (possibly *R. cuneifolius* × *argutus*).
R. trivialis: Manatee, Rogers, Advance.
R. loganobaccus: Logan.
R. loganobaccus × (*R. baileyanus* × *argutus*)*:* Young, Boysen.

Great Names in Blackberry History

The important names in blackberry history include W. O. Focke; H. Sudre, E. Brainerd and A. K. Peitersen, L. H. Bailey, B. Lidforss, J. H. Logan, and B. M. Young.

Focke was a German botanist with a broad viewpoint who made the study of the systematic botany of the blackberry-raspberry group a large part of his life work. He (*25*) divided the genus into subgenera and species in an understandable way. He described 132 species of

[3] Double-blossom or rosette disease is caused by a species of *Cercosporella* fungus which infects the buds causing a rosette or witches'-broom type of growth. The infected blossoms become distorted and are sterile.

blackberries. He gave a discussion of the origin of European blackberries to which reference is made in the appendix

Sudre (*54*), a French botanist, confined himself to the European blackberries. He tried to determine the original species of Europe by a study of their distribution and relationships and of the percentage of good pollen in their flowers. He described 110 species for all Europe.

Brainerd and Peitersen (*6, 44*) worked chiefly in Vermont and elsewhere in New England. In their two bulletins on the blackberries of New England they give an understandable grouping of the wild blackberries of the eastern United States. The two men made extensive field surveys, grew the wild forms side by side under cultivation, and made many crosses and many experiments on the effect of climatic conditions on the different forms. They describe 12 species for New England and refer many of the cultivated varieties to the species or their hybrids. Experiments in shading parts of plants showed that leaves of plants in heavy shade had less than one-seventieth the number of hairs and far fewer prickles than leaves in the sun. Canes in the shade were trailing, but those in the open were erect. The work showed (1) that the species of eastern North America and most hybrids were self-sterile or nearly self-sterile; (2) that hybrids had a large percentage of aborted pollen; and (3) that the hybrids showed segregation.

Figure 3.—B. M. Young, of Morgan City, La., at about the time he originated the Young dewberry (Youngberry) over 30 years ago. Mr. Young is still breeding raspberries and blackberries.

Bailey (*3, 4, 5*) has compiled much information regarding the history of both the cultivated and the wild blackberries and has made extensive field collections of both. He has issued a series of monographs on his interpretation of the wild species and has described many new forms.

Lidforss's studies (*34*) on inheritance in European blackberries, which were published in 1914 after his death, furnish an account of the development of the wild European blackberries. He obtained true and false hybrids in crosses and in selfing. The true hybrids always split in the second generation, while the false hybrids reproduce the mother exactly. In the false hybrids (1) no seed development occurs without pollination; but (2) when the flowers are pollinated false seed develops; (3) this false seed apparently does not develop from the ovule but from a cell in the wall of the ovary; and (4) the plants grown from such false seed are just as like the mother plant as if

propagated from a rooted tip or a root cutting. Gustafsson (*28*) also studied the development of false hybrids. Some European forms produce these false seedlings only; others may produce some true and some false, while others produce all true seedlings. Thus in Oregon and Washington the Evergreen and Himalaya blackberries usually reproduce each other exactly from these false seeds, and hundreds of thousands of wild plants occur that are just as alike as if they had been propagated by root cuttings or by tip plants (*20*). Only rarely are true seedlings of these two varieties found.

B. M. Young, of Morgan City, La. (fig. 3), produced a hybrid between the Phenomenal (very similar to Logan) and the Mayes

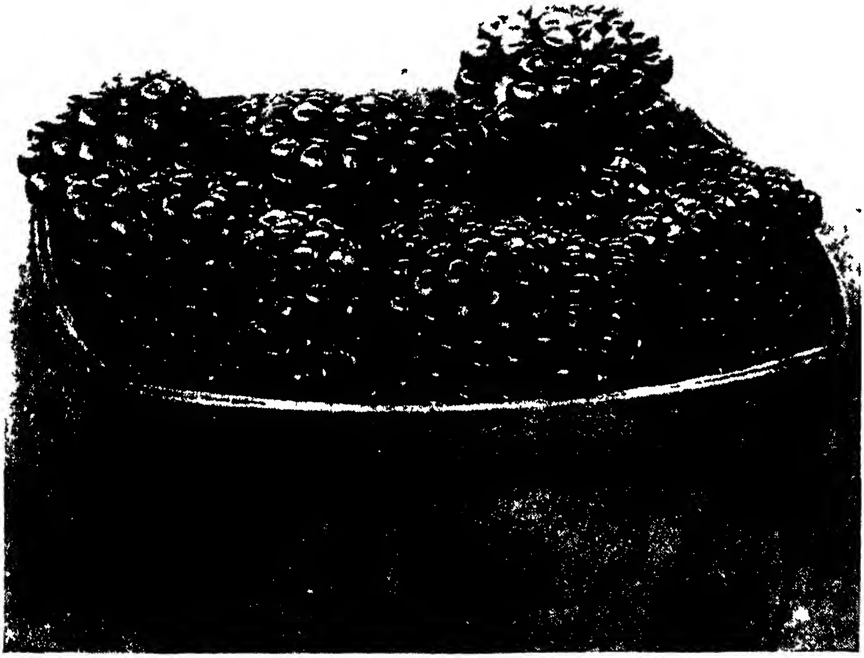

Figure 4.—The Young dewberry or trailing blackberry (Youngberry), one of the finest-flavored, largest, and most productive varieties; a cross of Phenomenal × Mayes.

dewberry or trailing blackberry about 1905. It was not introduced until about 1926, but it has quickly become an important sort (Young dewberry, or Youngberry, fig. 4), replacing the Logan to a large extent in California and to some extent in Oregon and Washington. In regions to which it is adapted it is the finest in flavor of all the blackberry group. Though Young has done extensive berry work since then, he has introduced no other variety.

The Logan and Its Relatives

The origin of the Logan is not yet fully explained. As stated above, in 1881 Judge Logan, at Santa Cruz, Calif., grew seedlings of a very rank-growing trailing blackberry, the Aughinbaugh. It was

pistillate-flowered, so that the flowers must have been pollinated either by wild male blackberries nearby, by an eastern erect blackberry in his garden, or by a red raspberry. Among about 100 seedlings there was the one later named Logan (fig. 5) with large, deep-red fruits. Judge Logan assumed that it was a cross of the black-fruited Aughinbaugh with the red raspberry. In recent years several facts have thrown doubt on this: (1) Blackberry-raspberry hybrids are mostly sterile, and if they do fruit they neither pick off like the blackberry nor pull off like the raspberry, but mash in the hand, while the Logan picks off like a blackberry. (2) Seedlings of the Logan

Figure 5.—The Logan blackberry (Loganberry), derived from the western trailing blackberry.

are all red-fruited and pick off like a blackberry. They vary in size, sweetness, season of ripening, vigor, etc., but show no distinct raspberrylike characters. (3) Cytologically the Logan seems like a pure species (*22*). Chromosome pairing is regular and reduction division is quite normal as for a pure species, not abnormal as in hybrids. It has 42 chromosomes, while the raspberry has 14. Plants of the species nearest like the Logan have 42 as the most common number. (4) Many hybrids of the Logan with selections of the wild blackberry are fertile, while most crosses of the Logan with the raspberry are not.

On the other hand, blackberry-raspberry hybrids resemble the Logan in habit of growth and to some extent in type of fruit. The red-fruited wild blackberries of the Pacific coast so far observed are much lighter red than the Logan. Perfect-flowered self-fertile selections of the wild observed so far differ considerably from the Logan.

Further study of the wild blackberries of the West, as grown under cultivation, and hybrids with the red raspberry and blackberry should do much to unravel the origin of the Logan. The evidence at hand indicates that the Logan is most probably a red-fruited sport of the wild blackberry.

Evolution of the Blackberries of Europe

There are two great centers of wild blackberries, eastern North America and Europe. According to Focke (*25*), the European and American species were separated in comparatively recent time, geologically speaking, probably by the southern movement of glaciers in the ice age. He holds that there are some 15 general types with a few more species to which all European blackberries can be referred. Sudre (*54*) came to a similar conclusion. Gustafsson (*28, 29*), of Sweden, concluded that when the ice age brought two widely different species groups together so that they hybridized, many of the pseudogamic blackberries of Europe that come true to seed originated. Because they came exactly true to seed they could reproduce themselves down through hundreds and thousands of years and eventually became widely distributed. ✓ At the present time in Europe there are thousands of forms of blackberries. Some few are good species; more are ancient hybrids that are more or less widely distributed; and many others are pseudogamic forms resulting from hybridizing, of which Oregon Evergreen and Himalaya are representative in this country. The Brainerd (*23*), which originated as a cross of Himalaya and an American variety, reproduces to some extent by pseudogamy, though no purely American variety is known to reproduce in this way.

Crane refers to *Rubus thyrsiger* Banning and Focke, *R. nitidioides* Watson, *R. borreri* Bell Salt., *R. laciniatus* Willd. (Evergreen), *R. rusticanus* E. Merc. and its variety *inermis* Willd., *R. schlechtendahlii* Wiehe, *R. calvatus* Blox. (Edward Langley), and *R. procerus* (Himalaya) as being European blackberries of possible value for breeding, *R. thyrsiger* and *R. nitidioides* have very large clusters of good-sized fruit of excellent flavor. *R. borreri* is early for a European blackberry. *R. rusticanus* is late and small-fruited, but hybrids are cultivated varieties. *R. inermis* is a thornless form of *R. rusticanus*.

Thornless Sports of Blackberries

Productive thornless sports of the Evergreen, Logan, Mammoth, and Young have been found, propagated, and introduced. Bud sports in general are considered to be due to the appearance of recessive characters, and this is probably the case with these blackberries. However, these productive thornless sports are all chimeras, having a thin layer of thornless tissue overlying thorny. Whenever they are propagated by root cuttings, or when the canes freeze back so that shoots come up from below the crown, they are always thorny. Seedlings of the thornless Evergreen raised by the writer, and seedlings of other thornless sports raised by H. M. Butterfield, of the University of California, have all been thorny.

Most thornless sports have been unproductive, and thornlessness may be linked with sterility (*19*). For a thornless sport to be productive the thornless tissue around the outside of the cane apparently

should be thick enough to prevent the production of thorns, but not thick enough to form the tissue that produces flowers and berries. If the thornless layer is relatively thick so that flowers are produced from it, then the flowers seem to be entirely or nearly sterile.

Breeding Work at Experiment Stations

Compared with other berries, little systematic breeding work has been done with the blackberries. The aims of experiments now under way probably represent some of the most worth-while objectives.

At the Rhode Island Agricultural Experiment Station the origination of hardy thornless forms is being studied. The first crosses were made in 1929. Thornless sorts such as *Rubus canadensis*, Austin Thornless, Cory, and Thornless Young have been crossed with Snyder, Eldorado, Alfred, Lucretia, and Gardena.

At the New York (State) station the first crosses were made in 1912, and some have been made from time to time ever since, notably a considerable number in 1927. Eldorado has been crossed with Agawam, Rathbun, Joy, Best of All, Brewer, Buckeye, and Erskine Park; Erskine Park with Rathbun and Buckeye; Rathbun with Agawam and Snyder. Agawam has been selfed and crossed with Snyder; Buckeye with Joy; Mersereau with Snyder. Strawberry Flavored has been selfed. The Eldorado × Brewer cross is considered a good one.

At the North Carolina station dewberry breeding began in 1926. Young and Lucretia were crossed, and the first-generation selections have been backcrossed in an attempt to obtain productive, disease-resistant, high-flavored, thornless sorts. The Cameron variety has been selected, propagated, and named for its vigor, high flavor, firmness, thornlessness, and resistance to anthracnose, to septoria leaf spot, and to nematodes, and D-3 and D-4 for the size of their cluster. In a cross of Young × Austin Thornless there were 334 thornless and 411 thorny in the first-generation progeny.

At the Texas station breeding work began in 1909. Ness (*41*) crossed a selection of the southern dewberry, *Rubus trivialis*, with the Brilliant red raspberry in 1912. The first and second generations were quite sterile except for five of the second-generation (open-pollinated) plants. These gave rise to a third generation, from which selections were made that were introduced as Nessberry in 1921. The Nessberry was then backcrossed with the dewberry, two raspberries, and a blackberry. The resulting progenies have been selfed for two to four generations.[4] The Nessberry is drought-resistant and has high flavor, but the fruit does not separate from the stem like either a blackberry or a raspberry. The obtaining of fertile seedlings in the third and fourth generations indicates that it may be possible through backcrossing to obtain seedlings the fruit of which will separate either like a raspberry or like a blackberry. Other breeding begun by Yarnell in 1934 (*57*) involves crosses and selfing of Young, Early Harvest, Hall Lawton, Crandall Early, Early Wonder, Lucretia, Dallas, Haupt, and Mayes.

---

[4] S. H. Yarnell (*57*), who has carried on the work in recent years, found that the Nessberry ($n=14$) has twice the chromosome number of its parents ($n=7$), and he concluded that its fertility was due to chromosome doubling. Plants of the F_3 of Nessberry ($n=14$) × Hallsham red raspberry ($n=7$), and plants of the F_4 of Nessberry × Early Harvest blackberry all had the 14 ($2n=28$) chromosome number and were fertile.

Breeding Work of the United States Department of Agriculture

The first crosses in the blackberry-breeding work of the United States Department of Agriculture were made in gardens in Atlanta, Ga., in 1919, and the seedlings were raised at Glenn Dale, Md. Only two seedlings grew to maturity, one of which was named the Brainerd (fig. 6) (*23*). It is a cross of Himalaya with an erect garden variety, probably the Georgia Mammoth The Brainerd is grown commer-

Figure 6.—The Brainerd blackberry, a cross of Himalaya on an erect-growing eastern variety. Note the large clusters of this variety. It is being grown in western Oregon for shipping and canning.

cially at Gresham, Oreg., for canning and shipping, replacing Himalaya for that purpose. It was hardy in Maryland until the winters of 1934–35 and 1935–36, when it was injured by temperatures of −17° and −23° F. Later crosses made at Beltsville, Md., and Willard, N. C., were between cultivated varieties such as Joy, Eldorado, Jumbo, Mersereau, and Blowers, while Eldorado and Joy were selfed. Recent crosses have been between Himalaya and Evergreen, Joy, Snyder, Early Wonder, Austin Thornless, Taylor, Lawton, and Eureka. The objective is to combine the size of fruit and hardiness of eastern varieties with the productiveness and vigor of the Himalaya. In these crosses a large proportion of the first-generation hybrid plants are true Himalaya, due to the development of "false" seedlings in this variety of the European type. In the crosses of Himalaya with American varieties 64 percent were maternal, that is, just like Himalaya, and 36 percent were true hybrids. In the cross Himalaya × Thornless Austin, about half of the true seedlings are thornless.

The breeding work at Corvallis, Oreg., is chiefly directed toward combining the high flavor of the native trailing blackberry with the size, firmness, productiveness, and hardiness of commercial varieties. Selections of different types of the wild blackberry, as well as the Logan, Young, Ideal Wild, and Zelinski, have been used in crossing with one another and with Lucretia, Austin Thornless, Eldorado, Oregon, Evergreen, Himalaya, and Mammoth. Crosses of the Logan with Mammoth, Lucretia, and Young were mostly sterile (*22*), even though they have the same chromosome number. Many selections have been made from the wild and Logan crosses, some having the high flavor of the wild, which is considered the highest quality in all the dewberry-blackberry group. One Himalaya × Logan hybrid is fully fertile and fairly vigorous, the second generation showing segregation into an immense number of forms. Out of a population of 817 hybrids of Logan × Young, 2 very firm-fruited selections have been made, both having the deep wine-colored fruit of the Young.

Blackberry-Raspberry Hybrids in England

Besides the Nessberry discussed above, several hybrids between blackberry and raspberry have been raised in England. Among these are Laxtonberry (Logan × Superlative), Mahdi (Belle de Fontenay × common English blackberry), Veitchberry (November Abundance × common English blackberry), and Kings Acre. The Mahdi and Kings Acre have 21, Veitchberry has 28, and Laxtonberry 49 chromosomes in vegetative cells. The Veitchberry is the most fertile and productive. None of these hybrids, however, has proved of commercial value, though they are of good quality. Just as with the Nessberry, they do not separate readily from the stem like either a raspberry or a blackberry. Possibly they will need to be backcrossed with a raspberry or with a blackberry before seedlings can be obtained that produce fruit that can be picked readily. Gruber (*27*) in Germany is doing some work in crossing blackberries and raspberries to transfer the disease resistance of the blackberry to a raspberry.

Some Problems and Objectives of Blackberry Breeders

Among the most important objectives for breeders are hardier northern varieties, thornlessness, small seed, high flavor, firmness, and resistance to double blossom and orange rust. Sources of each of these desirable characters are known and are listed in the appendix. Thus, both *Rubus canadensis*, the thornless blackberry, and *R. pergratus* are native in northern regions where most cultivated varieties are not hardy. Austin Thornless, Burbank Thornless, Cameron, and *R. canadensis* are available for breeding thornless varieties. With their superior flavor, *R. pergratus* and *R. allegheniensis* for eastern and *R. macropetalus*, *R. ursinus*, Logan, Young, and Boysen for western blackberries furnish material for great improvement in dessert quality. Excepting *R. cuneifolia*, the most erect blackberries have the smallest seeds, though a large-fruited and large- but few-seeded trailing variety like the Young may not be objectionably seedy.

It may be possible to utilize some of the immense-fruited blackberries of northern South America in breeding (*45*). They belong to a very different group from North American blackberries; but it is possible that hybrids with this group might be large-fruited seedlings that would reproduce exactly from seed, as do certain European varieties resulting from wide crosses.

RASPBERRIES

History of the Raspberry

According to Hedrick (*31*), the first red raspberries were introduced into cultivation in Europe about 400 years ago. Three hundred years ago there were at least two varieties cultivated in England, but variety names were not applied until after 1800. The European varieties were introduced into the United States even before 1800 and at first were raised even more extensively than were selections of native American raspberry. Probably one or more selections of the American red raspberry were in cultivation by 1800. The first named black raspberries were probably the Doolittle, introduced by H. H. Doolittle, Oaks Corners, N. Y., about 1850, and the Ohio Everbearing, found by Nicholas Longworth, Cincinnati, Ohio, in 1852.

A Dr. Brinkle, of Philadelphia, Pa., was the first successful raspberry breeder of this country. He originated many varieties of raspberries, among which was the high-flavored Orange (Brinkles Orange). This he raised from seed in 1845. Although there was a considerable acreage of raspberries around some of the larger cities, it was nearly 1870 before the raspberry became a crop of any great importance. The Cuthbert variety was found as a chance seedling in 1865 in what is now a part of New York City; it was probably a cross of Hudson River Antwerp, a European variety, with a wild native red. Ever since the introduction of the Cuthbert, which is still the chief variety of the Northwest, the raspberry has been an important small fruit. Cuthbert and Ranere (St. Regis) are the only important varieties of red raspberry now grown that originated as chance seedlings.

Other leading red raspberries are Latham, Chief, Ohta, Marlboro, and King, all of which resulted from definite attempts to improve the

raspberry. The Marlboro was originated by A. J. Caywood, Marlboro, N. Y., before 1880, and at one time was the leading variety. The Latham originated at the Minnesota Fruit Breeding Farm as a cross between King and Loudon, and was introduced in 1912. Since then it has become the leading variety east of the Rocky Mountains. The Ohta, Chief, June, and Newburgh are other varieties from experiment stations that have succeeded.

✓ The leading black raspberries, Cumberland in the East and Munger in the Northwest, both resulted from growing seedlings, the Munger coming from seed of the Shaffer Purple. Quillen, an anthracnose-resistant variety grown in the Midwest, resulted from a cross between Cumberland and Hopkins. The other black raspberries grown to any extent commercially originated as chance seedlings. Recently, however, the New York (State) Agricultural Experiment Station, at Geneva, has introduced four black raspberries that seem to be succeeding.

The most important of the purple varieties, Columbian, was grown from seed of Cuthbert. Recently the Potomac and Sodus purple varieties have been introduced. Both are succeeding and are adapted to a wider range of conditions than Columbian. The Potomac is one of the hardiest of all raspberries.

American and European Raspberries

The commercial cultivated raspberries of the world have come from the wild red raspberry of Europe (*Rubus idaeus* L.) and the red (*R. strigosus* Michx.) and black (*R. occidentalis* L.) wild raspberries of North America (*16*).

Rubus idaeus is native in much of Europe, but closely allied forms occur across northern Asia to Japan. It is much like the North American red raspberry, but in general is not so hardy and usually has stout purple prickles, larger leaves, and duller and more conical berries. The largest size in cultivated berries has come from the Lloyd George and Pynes Royal varieties, which are derived from this species.

The American red raspberry, *Rubus strigosus*, is native in the mountains from Georgia to Pennsylvania and in both lowlands and mountains from Maine to the Dakotas, far north in Canada, and west to British Columbia. Allied forms occur in the Rocky Mountains. It has much greater hardiness than the European species, the canes are more slender and often more erect, the prickles are not so stout and sometimes are absent. The berries are seldom thimble-shaped and are usually bright red. The species is extremely variable in the wild.

The American black raspberry, *Rubus occidentalis*, has much the same range in the United States as *R. strigosus*, but ranges as far south as Oklahoma, Atlanta, Ga., and the lowlands of Virginia. It is not so hardy as the wild red raspberry, and although found from North Dakota and Quebec to Maine and New Brunswick, is far less common than the red raspberry toward its northern limit. A closely allied species, *R. leucodermis* Dougl., occurs from British Columbia to California.

The black raspberry has a sweeter but a more seedy fruit than the red. Curiously, though, yellow- or amber-fruited black raspberries

are common, and yellow and amber colors are common in the red raspberries of Europe, these colors are rarely found in American wild red raspberries. Natural hybrids between the black and the red, called purple raspberries, occur quite commonly in some sections. The purple raspberries are more vigorous and if fertile are more productive than either the red or black. The fruit is often larger and usually has more pulp or flesh in proportion to the seed.

Related berries that are often called raspberries are the two flowering raspberries of the woods, *Rubus odoratus* L. and *R. parviflorus* Nutt., with large, showy, purplish-red and white flowers and soft, thin-fleshed berries; the salmonberry, *R. spectabilis* Pursh, a perennial-caned tender species of the Pacific coast with large berries not in clusters; and the baked-apple berry, *R. chaemaemorus* L., of the bogs of northern Canada, Alaska, northern Europe, and Asia.

Future Raspberries

Three other raspberries are grown slightly in some parts of the world —the Andes black raspberry (*Rubus glaucus* Benth.) in northern South America; *R. niveus* Thunb. (*R. lasiocarpus* Sm.) in northern India and Burma; and the wineberry (*R. phoenicolasius* Maxim.), introduced from Japan, in the northeastern United States. Besides these 6 kinds, the Van Fleet, grown to some extent in the Southern States, is a cross of Cuthbert and *R. kuntzeanus* Hemsl., a Chinese raspberry (*17*).

The possibilities of improving the raspberry by utilizing just these seven species are enormous. The very large size of the varieties now in cultivation in Europe, such as Lloyd George, Pynes Royal, and the new Imperial, as well as of Marcy and many recent selections at the Geneva, Corvallis, and Puyallup stations, would hardly have been thought possible 10 years ago. Some of the qualities to be combined in raspberries of the future are the firmness of the Newburgh, U. S. D. A. No. 9 (Latham × Ranere), and Potomac; the vigor of Van Fleet; the productiveness of plants of Dixie and Van Fleet; the immense fruit clusters of *Rubus kuntzeanus* (fig. 7); the resistance to cold of Ohta, Sunbeam, Latham, Chief, Potomac, and Sarah and some other Canadian varieties; the resistance of Van Fleet and Quillen seedlings to anthracnose; of Lloyd George and Newburgh to mosaic-carrying aphis, and of Cuthbert to verticillium wilt.

The cultivated raspberries, however, are but a small part of the raspberries of the world. Focke (*25*), in his latest book on the subject of raspberries, published some 20 years ago, described 195 wild kinds of eastern and southern Asia alone. These range from whole groups with vines and leaves much like those of the grape to others with leaves like the hawthorn, bamboo, viburnum, maple, and apple. Some have soft, others woody stems. Some are low plants, while *Rubus ellipticus* Sm., the Golden Evergreen raspberry, may have canes 3 inches in diameter and grow 14 feet high (fig. 8). Eastern Asia is the center of the wild raspberries of the world.

Some of the species of Asia and elsewhere are already being crossed. The Hawaiian station and the Armstrong nurseries are working with several forms of the Akala raspberry of Hawaii. Crosses have been made between both *Rubus biflorus* Buch., a Chinese species, and the

Figure 7.—*Rubus kuntzeanus*, a very large-clustered, vigorous species of raspberry from Asia, with red, wine, and black fruit. The Van Fleet resulted from a cross between this species and Cuthbert.

salmonberry, *R. spectabilis*, and red-raspberry varieties at the Corvallis station. At the Willard and Beltsville stations and at the Tennessee station *R. kuntzeanus* of Asia and the Van Fleet are being used. At the United States Horticultural Field Station, Cheyenne, Wyo., *R. deliciosus* Torr. of the Rocky Mountains is being crossed with red raspberries. At the Beltsville and Willard stations there are about 2,000 crosses of *R. parvifolius* L. (fig. 9), an Asiatic trailing raspberry, with red, black, and purple varieties. *R. niveus* has been used by B. M. Young, of Morgan City, La., and at the Beltsville

Figure 8.—**A single plant of the Golden Evergreen raspberry, *Rubus ellipticus*, 14 feet high and 26 feet across. Some of the canes were 3 inches in diameter. (Watsonville, Calif.)**

station. William E. Whitehouse, of the Department, has succeeded recently in introducing several other species, and they are now available to breeders. The woolly raspberry, *R. lasiostylus* Focke (fig. 10), is a very large-fruited species from Asia. All the raspberry species so far studied have seven chromosomes in the reproductive cells, as have most cultivated varieties. Raspberry species so far tried in breeding have crossed readily, though many of the seedlings have not been fertile. Some of these species that have superior germ plasm of value are: For size of fruit, Akala and *R. biflorus*; for vigor of plant, Golden Evergreen (*R. ellipticus*) and *R. biflorus*; for resistance to disease, *R. biflorus*, *R. ellipticus*, *R. coreanus* Miq. (fig. 11), the Andes berry (*R. glaucus*), *R. kuntzeanus*, *R. innominatus* Moore. Most of the breeding work with raspberries lies ahead.

Raspberries and Blackberries of Unusual Colors

In the raspberry there are yellow- or golden- and apricot- or amber-colored berries as well as black, red, purple, and various shades of color from red to purple and purple to black. The yellow and apricot

colors are found in seedlings of the European red and in varieties derived in part from the European, such as Cuthbert and Herbert, but never, so far as known, from the American red. In black raspberries, the yellow form is common in the wild, especially in Maryland.

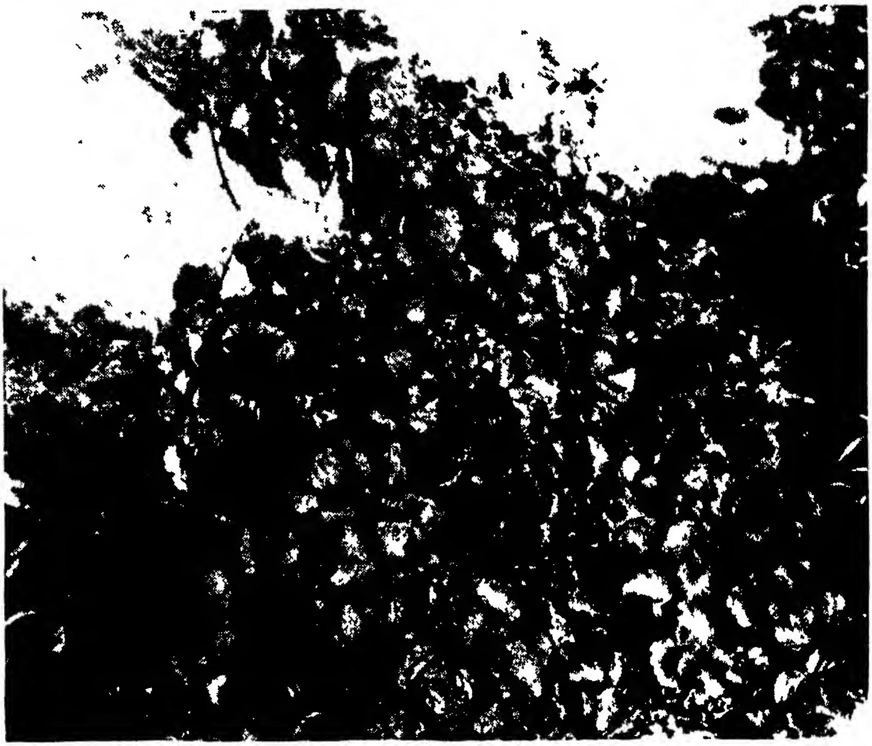

Figure 9.—Rubus parvifolius, the trailing raspberry of Japan and eastern China, which is very disease-resistant in the United States. Selections of this species are promising in southern States, and hybrids with red, black, and purple varieties are being fruited.

The introduced species of raspberries from Asia have a great variety of colors, ranging through red, orange, yellow, lavender, purple, and wine color to black.

In the blackberry, the white or pale yellow is rather commonly found in the wild in many and possibly all species in North America as well as in many species in Europe. Pink selections have been seen in Alabama and in Oregon, while lavender-colored ones have been reported in North Carolina. In the West the wild blackberry often is not quite black but a very deep wine color.

Raspberry Breeding at State Stations

At the New York (State) Agricultural Experiment Station (*50, 51, 56*) at Geneva, the first crosses were made in 1892, and the work has been continued to the present. Over 250 different crosses have been made and over 15,000 seedlings raised. Of these crosses 130 were of

red raspberries, 27 were of black raspberries, and 93 were with or for purple raspberries. For the breeding work the station maintains a collection of some 38 species of raspberries and blackberries, 33 varieties of red raspberries, 18 of black raspberries, and 7 purple varieties.

Figure 10.—Rubus lasiostylus, a very large-fruited species from Asia, the fruit of which is covered with a thick mat of hair. The upper fruit is ripe. (Natural size.)

There still are 41 station selections under test for possible introduction. Besides many commercial varieties, 55 of their own selections have been used in the breeding work, as well as the named varieties that have been introduced by the New York station.

Of the red raspberries, George L. Slate, who has had charge of the berry breeding for many years, states that Lloyd George, Newman, Herbert, and Loudon have been exceptional parents. Cuthbert has not been so good a parent, though it has transmitted its high flavor and canning quality in some crosses. Erskine Park, Buckeye, Count, Douboro, Empire, Owasco, Syracuse, Gold Drop, Ohta, Ranere, Superlative, Newman 20, and Marldon have been poor parents in the crosses made. Selfed populations resulted in dwarfs, weaklings, a high proportion of seedlings lacking hardiness, and a considerable amount of partial and complete sterility. Establishment of inbred lines has not been made a part of the breeding program because of (1) the long

time between generations, (2) the high proportion of the weaklings, dwarfs, and otherwise inferior seedlings, and (3) the difficulty of maintaining a number of inbred lines because of virus diseases, winter injury, and lack of vigor. Slate states: "The vast possibilities of improving raspberries by variety crossing make this method the

Figure 11.—***Rubus coreanus*, an Asiatic black raspberry resistant to leaf and cane diseases that is promising for breeding for southern States.**

most promising line of attack in red raspberry improvement at this station."

Many hybrids, backcrosses, and selfed seedlings have been raised involving crosses with blackberries. Among these crosses are:

Mahdi × Herbert
(Mahdi × Herbert) × (Newman × Herbert)
(Mahdi × Herbert) × Herbert
(Mahdi × Herbert) × Lloyd George
Mahdi × Phenomenal
Mahdi × Lucretia
Mahdi × Mersereau
Mahdi × (Mahdi × Lucretia)
Mahdi × *Rubus odoratus*
(Mahdi × Herbert) selfed
(Mahdi × Lucretia) selfed
(Mahdi × Lucretia) × Herbert
(Mahdi × Lucretia) × Snyder
Herbert × Logan
Cuthbert × Logan
Latham × Logan
Donboro × Logan
(Herbert × Logan) selfed
Rubus phoenicolasius × Agawam
R. phoenicolasius × Empire
(*R. phoenicolasius* × Empire) selfed
(*R. phoenicolasius* × Empire) × Empire
Smith No. 1 (black raspberry) × Snyder
Kansas × Agawam
Kansas × Mayes
Mammoth × Agawam
Mammoth × Cuthbert
Mammoth × Herbert
Mammoth × Snyder

Thus, the Mahdi, a raspberry × blackberry cross, has been backcrossed with both the raspberry and the blackberry, and the progeny

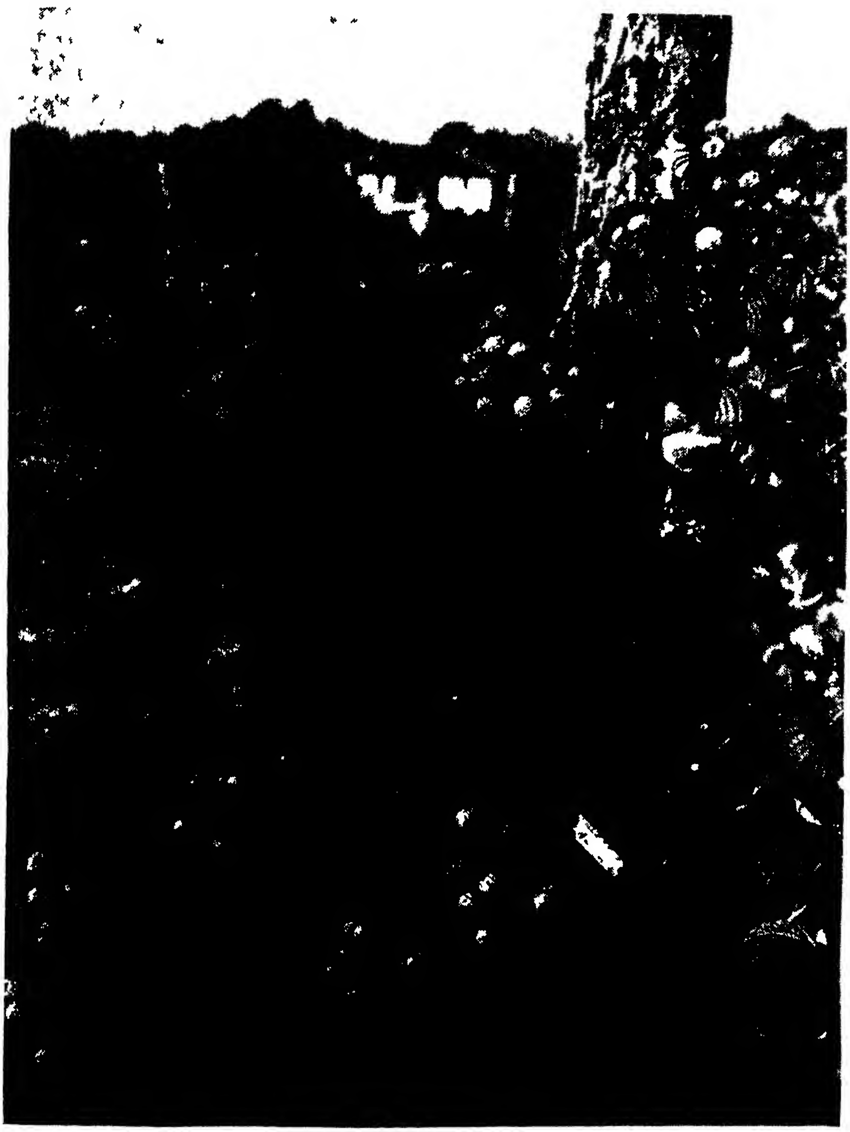

Figure 12.—A hybrid seedling with a desirable fruiting habit. Note exposed fruit, which makes picking easy.

backcrossed a second time with each. So far no selections have been introduced.

Thirty-four different crosses between the black and the red raspberries, 19 different selfings, some 21 different backcrosses with red, and 19 second backcrosses with red have been made. Over 4,300 seedlings have been raised (fig. 12), and 3 varieties have been intro-

duced, of which Brant and Sodus are first crosses and Webster is a backcross of a black and a purple. Backcrossing is still considered promising in this group. Typical red and black raspberries have not appeared when the hybrids were selfed or when purples have been crossed with purples. Dundee × Newburgh has been considered one of the most promising crosses. Besides hybrid vigor, drought resistance has been noted in the purple raspberries.

With the black raspberry, emphasis has been placed on size, color, firmness, and quality of berry, and vigor, yield, and hardiness of plant. Cumberland, Dundee, Eureka, Farmer, Grant, Gregg, Hilborn, Honeysweet, Kansas, Lane, Palmer, Rachel, Smith No. 1, and Watson Prolific have been used in crosses.

At the South Dakota station (*30*) many thousands of seedling raspberries have been grown, particularly crosses of cultivated varieties with selections of the wild red raspberry that have proved fully hardy at Brookings, with no winter protection. Sunbeam and Ohta (Flaming Giant) are two of the eight named selections resulting from the crosses that have proved to be adapted to the climatic conditions of eastern South Dakota.

At the Illinois station raspberry breeding (*1*, *2*, *8*, *9*, *10*) was begun in 1922 and over 14,000 seedlings are now under test. Some 121 selections have been made for further observations. The Quillen, Farmer, Older, Munger, and Pearl black varieties and Latham, June, Starlight, Newburgh, Ulster, and Taylor red sorts have been used in this work. Among the best crosses for purple varieties are Quillen × June, Quillen × Latham, and Quillen × Newburgh. In a study of the inheritance of anthracnose resistance, 52 percent of the selfed seedlings of Quillen were free from anthracnose, and no selfed seedlings of Cumberland, Pearl, Farmer, Honeysweet, Older, Munger, Royal Purple, Earheart, or Conrath were free. Of 661 Quillen selfed, 622 had reddish-brown canes and 34 yellow canes. Of 105 Pearl selfed, 96 had reddish-brown canes and 9 yellow, close to a 15:1 ratio. When Cumberland was selfed, all 452 seedlings had reddish-brown canes.

At the Washington State station at Puyallup raspberry breeding was first begun in 1909 (*33*). No varieties were introduced from the early work. In 1928 new breeding work was begun to obtain varieties hardier than Cuthbert, which would be satisfactory for canning, freezing, and shipping, and resistant to mosaic. Selections of Cuthbert and Lloyd George parentage are especially promising. Inheritance of fruit characters and of winter hardiness has been made an important part of the study (*48*, *49*).

At the Minnesota station the breeding work has been notable for the origination of Latham and Chief red raspberries, the Latham being the leading red variety of the eastern United States. It is estimated that at the present time there are about 25,000 acres of Latham and 3,000 acres of Chief grown. The work is being continued, and many black and red selections are now being tested. Among the principal varieties crossed are Latham, Chief, Herbert, Ranere, King, Lloyd George, Cuthbert, selections of the wild, and the Farmer and Platt black varieties. The Farmer and Platt black and the Chief red varieties have been inbred. E. Angelo, in charge of the work at

present, emphasizes the need for studies on the mode of inheritance of characters, breeding for disease resistance, and improving the flavor of the fruit.

Extensive breeding work began at the Tennessee station in 1931, using the Van Fleet for its disease resistance and vigor in the South, to cross with red varieties. Selections have been made and are being tested.

At the North Carolina station breeding was begun in 1926 to obtain varieties resistant to diseases and adapted to the South, by using Asiatic species, especially *Rubus biflorus*. One variety, Dixie, is being introduced in 1936–37. Although not large-fruited, it is one of the most productive of red raspberries and is desirable for home use. Beginning in 1936, the work was made cooperative with the Department.

Raspberry Breeding at United States Department of Agriculture Stations

The first raspberry breeding of the United States Department of Agriculture was done by W. Van Fleet while he was at the United States Plant Introduction Garden at Chico, Calif., in 1909 (*17*). He crossed *Rubus kuntzeanus*, a species from China, with the Cuthbert, and from the seedlings selected one that was later named the Van Fleet. The writer became associated with Dr. Van Fleet at the Department's station at Glenn Dale, Md., in 1920 and has carried on the breeding work since. The Potomac (purple) is the only variety introduced besides Van Fleet. The work at Beltsville, Md., and Willard, N. C., consists largely of (1) genetic studies, (2) hybridizing foreign species with cultivated varieties, and (3) crossing to obtain resistance to leaf spot, anthracnose, and leaf rust (*18*, *21*). At Willard, in cooperation with the North Carolina Agricultural Experiment Station, varieties adapted to the South are being bred, using foreign species in the crosses.

At Corvallis, Oreg., in cooperation with the Oregon station, a large part of the work is directed toward obtaining large-fruited varieties suitable for canning, freezing, and long-distance shipment. Inheritance of resistance to diseases is being studied in cooperation with the small-fruit pathologists. Red varieties used in crossing include Antwerp, Cayuga, Chief, Cuthbert, Herbert, Latham, Lloyd George, Newburgh, Ranere, and Viking; black varieties, Cumberland, Munger, and Farmer; and the purple variety, Potomac. Species used include *Rubus spectabilis*, the salmonberry, *R. leucodermis*, the western black raspberry, and several Asiatic species. Lloyd George × Newburgh crosses have been particularly promising, selections from these having larger fruit than any yet found.

At Cheyenne, Wyo., crosses are being made with the entirely hardy perennial-caned *Rubus deliciosus* in the attempt to obtain much greater hardiness.

Raspberry Breeding Abroad

Canada

Raspberry breeding was begun in Canada at Ottawa as early as 1873 (*38*), when William Saunders (*47*), later Director of the Experimental Farm at Ottawa, crossed the Doolittle (black) with the Philadelphia (dark red—a probable black × red hybrid) and obtained

24 purple-fruited seedlings. His work was transferred in 1887 to the Dominion station when he entered the Dominion service, and it has been continued since. At least 23 varieties have been introduced, of which 2, Brighton and Count, are still important varieties in Canada.

Raspberry breeding began at Vineland, Ontario, in 1913 (*43*). According to W. J. Strong, in charge of the work at present, some 125 crosses and 167 open and self-pollinations, using 16 varieties, resulted in 21,000 seedlings. About 140 selections were propagated, and one variety, the Viking, was named and introduced. This variety, introduced in 1924, is extensively grown in Ontario and is increasing slowly in importance in other sections in Canada and the northern United States. It is estimated that 1,500 acres of this variety are grown.

England

In England (*52*, *53*), extensive work in breeding raspberries by N. H. Grubb (*26*) at East Malling, Kent, has included selfing 19 varieties to study the inheritance of characters. Of 74 selfed seedlings of Pynes Royal, 22 were worthy of propagation, and of 92 selfed Lloyd George, 17 were propagated. Pynes Royal seedlings were much larger, but were mostly dark, hard to pick, and not of high flavor. Lloyd George seedlings produced many canes, but few had large fruit. Red Cross and Preussen, selfed, were very disappointing. Of 4 selections chosen for trial, all were from self-pollinated progenies of Royal × Lloyd George hybrids.

Chief emphasis has been placed by M. B. Crane and W. J. C. Lawrence (*11*, *14*, *15*), of John Innes Institute, Merton, on inheritance of characters such as sex, color of prickles and fruit, and hairiness. Two pairs of factors were found to determine sex, two color, and one hairiness.

Private Breeders of Raspberries

Several private breeders have valuable varieties to their credit, especially C. P. Newman, of La Salle, Quebec, Canada, and George Pyne, of Topsham, Devon, England. Newman (*42*) originated the Newman from seed of several varieties mixed. This variety is out-outstanding for its firmness of fruit, hardiness of cane, and mosaic resistance. It was introduced in 1919 and is still grown commercially. It is important as one of the parents of the Newburgh, Monroe, Taylor, Marcy, and Potomac raspberries.

Pyne selected Devon and Pynes Royal from self-sown seedlings and Park Lane and Red Cross from self-sown seedlings that he transplanted and tested. Mayfair came from seed of Park Lane, and Imperial from seed of Royal. Better-Late is a seedling of a blackberry-raspberry hybrid. The Red Cross is notable as an early productive sort with a long season, Park Lane and Mayfair for their high flavor, Pynes Royal for its large size, excellent flavor, and firmness, while Imperial is reported to be larger than Pynes Royal, which has been the largest raspberry known.

A third private breeder, George Adams, of Smithville, Ontario, has grown seedlings over a period of some 40 years, starting with purple and black varieties. His Adams 87 and Adams 101 are grown to a considerable extent in western New York. Adams 101 is a red variety rooting at the tips of canes, while Adams 87 is an especially hardy sort.

Generic Crosses

.Hybrids between raspberries and blackberries have been discussed above and the reported hybrids with the strawberry are discussed in the article on strawberry breeding in this yearbook. Hybrids of raspberries or blackberries with roses, apples, etc., have been reported, but no authentic cases are known. Van Fleet once stated that he had tried to cross the raspberry and a rugosa rose (*Rosa rugosa* Thunb.). He obtained sterile seedlings, which may possibly have been hybrids.

Everbearing or Fall-Fruiting Raspberries

The so-called everbearing raspberries produce a crop in the early summer at the same time as other varieties and later a second crop on the new canes. The Ranere (St. Regis) is the most common American red variety of this group. Erskine and La France are two others, and the New York (State) station has just introduced another, Indian Summer. These varieties form fruit buds on the most vigorous canes in midsummer, beginning at the tips and flowering and fruiting downward toward the base. Besides these, other varieties like the Lloyd George in Oregon and Washington begin to flower and fruit in September. Even some of the ordinary varieties such as Cuthbert may start flowering in September in some years. In the wild, fall-fruiting raspberries are often found.

Figure 13.—*A*, Red-raspberry buds and flowers. The bud at the lower left is ready to cross, or in warm, dry weather it may be so far advanced that pollen is already shedding. The other flowers are too advanced to use out of doors. *B*, After emasculating with scalpel, forceps, or the thumbnail, pollen is applied directly by twirling the flower so that the pollen is brushed from the anthers to the pistils. *C*, Blackberry flower with pistils in receptive condition and with some of the anthers on the outer stamens already split open and shedding pollen.

138904°—37——34

Summer- and fall-fruiting black raspberries are also rather commonly found in the wild, and several have been introduced. The Ohio Everbearing was one of the first black raspberries ever named and cultivated. However, fall-fruiting black raspberries are not very practicable, for fruiting on the tips of the canes interferes with propagation. So far, only with special care have they succeeded. Purple summer- and fall-fruiting raspberries present the same difficulties as do the blacks.

TECHNIQUE OF BLACKBERRY AND RASPBERRY CROSSING

Most of the breeding work with blackberries and raspberries is done out of doors, though when tender varieties are to be used it may be done with potted or tubbed plants in the greenhouse. Flowers of

Figure 14.—Flower clusters bagged after crossing, to protect from bees.

all except self-sterile kinds should be emasculated at least 1 day before the calyx begins to split, because in some varieties under certain conditions the anthers may open and shed pollen before the buds open (fig. 13). The thumbnail is commonly used to cut away the calyx, corolla, and anthers, and the operation does not seem to injure the setting of the flowers. In the field the flower clusters should be covered with ordinary paper bags to keep insects away (fig. 14). After 1 to several days the pistils are receptive and pollen is applied. Pollen may be gathered in a dish and applied with a small, soft brush, or a flower may be twirled between the fingers so that the pollen is brushed from the stamens onto the pistils of the flowers used as the female parent. The paper bags may be taken off the flower clusters

after the third day, or, in all except the windiest or rainiest weather, they may be left on to protect the clusters until the berries ripen.

The seed of the ripe berries may be cleaned or the berries crushed in dry sand. Though dried seed of some varieties and species may germinate if given suitable conditions, they are likely to require 2 or more years. For this reason, in the work of the Department the fresh seed is planted immediately, and the flats or pots of seed are stored in a cool, moist place and are exposed the following winter to 2 or more months of cold weather just above freezing. The soil in the flats is kept moist from sowing until germination. Good germination has followed this practice. Fresh seed of tropical species generally germinates at once. Occasionally seed of some raspberry varieties has also germinated immediately after planting. Under favorable conditions the seedlings can be set in the field in the spring, and by the following year many kinds may fruit.

APPENDIX

TABLE 1.—*Breeding work with blackberries at experiment stations*

Location	Past workers	Present workers	Year begun	Objectives
State stations:				
Georgia, Experiment	J. G. Woodroof	J. E. Bailey, H. L. Cochran, H. P. Stuckey.	1927	High-flavored southern varieties.
New Jersey, New Brunswick.		J. H. Clark	1928	Productive, disease-resistant sorts.
New York, Geneva		George L. Slate, R. Wellington.	1912	Hardy, productive sorts.
North Carolina, Raleigh.		C. F. Williams	1926	Thornless, high-flavored, disease-resistant, hardy sorts.
South Dakota, Brookings.	N. E. Hansen, Charles Haralson.			Hardy varieties.
Rhode Island, Kingston		A. E. Stene, T. E. Odland.	1929	Thornlessness.
Texas, College Station	H. Ness	S. H. Yarnell, H. F. Morris.	1908	Drought-resistant, high-flavored, productive hybrids.
Washington, Puyallup.	W. H. Lawrence, J. L. Stahl.		1909	Crosses of Evergreen and American varieties.
Department stations:				
Maryland, Beltsville (formerly at Glenn Dale).	W. Van Fleet, G. F. Waldo.	George M. Darrow	1920	Thornless productive Himalaya hybrids, Logan × eastern blackberry hybrids.
North Carolina, Willard.	G. F. Waldo	George M. Darrow, C. F. Williams.	1929	Do.
Oregon, Corvallis	C. E. Schuster, B. S. Pickett, George M. Darrow.	G. F. Waldo	1928	Thornless, firm, high-flavored hybrids of Logan, Himalaya, Evergreen, Eldorado, and selections of the wild.
Canada:				
Ontario, Lennoxville				
British Columbia, Sidney.				
England:				
Long Ashton, Bristol		J. G. Maynard, G. T. Spinks		Table and canning varieties.
John Innes Institute, Merton (*12, 13*).	W. O Backhouse	M. B. Crane, C. D. Darlington	1911	Genetics and thornlessness.
Union of Soviet Socialist Republics:				
Michurin Institute (*39, 46*).	I. V. Michurin	A. Petrov, V. G. Lithovitzer		Hardiness.

TABLE 2.—*Blackberry varieties originated by public agencies*

Location	Variety	Year introduced	Parentage	Superior qualities
State stations:				
North Carolina, Raleigh.	Cameron	1936–1937	Young × Lucretia	Disease resistant, thornless, high flavor.
South Dakota, Brookings.	Siberian	1930	Seedling of wild from Siberia.	Hardy dewberry.
Texas, College Station.	Nessberry	1921	*Rubus trivialis* × Brilliant raspberry.	High flavor, drought resistance.
Department stations:				
Maryland, Beltsville (formerly at Glenn Dale).	Brainerd	1932	Himalaya × erect eastern variety.	Vigorous, productive.
England:				
John Innes Institute, Merton.	John Innes		*R. rusticanus inermis* × *R. thyrsiger*.	Large, late, long seasons.
Long Ashton, Bristol.	Ashton Cross	1932	Seedling of wild	Large, bright, productive.
Union of Soviet Socialist Republics:				
Michurin Institute (*39*).	Abundant		Seedling of Lucretia	Hardy.

TABLE 3.—*Blackberry varieties originated by private agencies*

Name and location	Variety	Year introduced	Parentage	Superior qualities
B. M. Young, Morgan City, La.	Young	1926	Phenomenal × Mayes	Disease resistance, excellent flavor, large.
Laxton Bros., Bedford, England.	Bedford Giant	1934	Veitchberry seedling	Early for European type, large.

SOURCE OF SUPERIOR QUALITIES IN BLACKBERRIES

Plant Characters

Hardy against cold. *Rubus pergratus, R. canadensis, R. allegheniensis*, Snyder, Eldorado, Ancient Briton, Agawam.

Resistant to orange rust. Eldorado, Oregon Evergreen (Black Diamond), Russell, Snyder.

Resistant to double blossom. Himalaya, Rogers, Advance (may be same as Rogers).

Resistant to root nematode. Hall Lawton, Young, Crandall.

Resistant to crown gall. Austin Thornless, Advance.

Resistant to leaf spot (septoria). Young, Himalaya, Evergreen, Boysen, Early Harvest.

Resistant to anthracnose. Young, Boysen.

Resistant to verticillium wilt. Himalaya and Evergreen, immune; Logan and Mammoth, resistant.

Thornless (genetically thornless). Austin Thornless, *R. canadensis*, Burbank Thornless, Cameron.

Vigorous. Himalaya, Evergreen, Brainerd, Logan, *R. macropetalus, R. ursinus*, Young, Boysen; Haupt in Texas, Eldorado in North.

Resistant to drought. Nessberry.

Large flower clusters. *R. thyrsiger, R. nitidioides*, Himalaya, Evergreen.

Fruit Characters

Early ripening. Advance and Rogers (earliest), McDonald, Haupt, Lucretia, Young, Mayes, Early Harvest, Wilson Early; *R. borreri* of Europe.

Late ripening. Burbank Thornless, Himalaya, Evergreen, Brainerd, *R. cuneifolia*, Nanticoke, Eureka; *R. rusticanus* of Europe.

Firm. Oregon (Logan × Young), Advance, Evergreen; Mersereau of eastern blackberries.

Large. Boysen, Young, Mammoth, Logan, Eldorado, and Brewer.

Do not turn red in shipment.—Brainerd.

Canning. Evergreen in Oregon and Washington; Brainerd, Young, Boysen, Logan, Ideal Wild.

Freezing. Young, Boysen, Cameron, Logan.

Excellent flavor. Ideal Wild, Zelinski, Young, Boysen, Logan, *R. macropetalus* of western type; Cameron, Eldorado, Brewer, *R. allegheniensis, R. pergratus.*

Small seed. Early Harvest.

Lack of seediness. Young, Boysen.

TABLE 4.—*Breeding work with raspberries at experiment stations*

Location	Past workers	Present workers	Year begun	Objectives
State stations.				
Arkansas, Fayetteville.		J. E. Vaile	(1)	
Colorado, Loveland	R. V Lott		1930	(Work transferred to Cheyenne, Wyo., 1936)
Connecticut, New Haven.		D. F. Jones, W. R. Singleton.		Value of inbreeding.
Georgia, Experiment	J. G. Woodroof	H. L. Cochran, H. P. Stuckey, J. E. Bailey.	1927	Southern variety of high flavor.

See footnotes at end of table.

Table 4.—*Breeding work with raspberries at experiment stations*—**Continued**

Location	Past workers	Present workers	Year begun	Objectives
State stations—Contd.				
Hawaii, Honolulu		W. T. Pope	1930	Crosses with native raspberries.
Illinois, Urbana	C. J. Alexopoulus	A. S. Colby	1922	Hardiness, disease resistance, high flavor, productiveness.
Iowa, Ames				Anthracnose resistance.
Maine, Orono		R. M. Bailey	1932	
Massachusetts, Amherst.		A. P. French	1934	Isolation of pure lines for later work.
Minnesota, Excelsior	Charles Haralson, M. J. Dorsey, J. H. Beaumont, S. B. Green.	W. H. Alderman, E. Angelo, F. E. Haralson.	1891 [1]	Hardiness.
New York, Geneva	S. A. Beach, O. M. Taylor, W. H. Alderman, R. D. Anthony, M. J. Dorsey	George L. Slate, R. Wellington.	1892	Disease resistance, fall fruiting, size of fruit, quality, productiveness.
North Carolina, Raleigh.		C. F. Williams	1926	Obtaining hybrids with Asiatic species for South.
North Dakota, Fargo		A. F. Yeager, D. H. Scott.	1920	Hardiness.
Ohio, Wooster	P. Thayer (*55*)			Genetics of yellow color.
South Carolina, Clemson College.	W. J. Young			
South Dakota, Brookings.	Charles Haralson	N. E. Hansen	1898	Hardiness.
Tennessee, Knoxville.	J. A. McClintock	B. A. Drain	1931	Better varieties through use of Van Fleet and *Rubus kuntzeanus*.
Washington, Puyallup.	M. B. Hardy, J. L. Stahl, W. H. Lawrence.	C. D. Schwartze	1909 [3]	Hardiness, mosaic resistance, adaptation to canning, freezing, and dessert.
Department stations:				
Wyoming, Cheyenne.		LeRoy Powers	1935	Resistance to cold and drought. Crossing *R. deliciosus*.
Maryland, Beltsville	G. F. Waldo	George M. Darrow	1920	Disease resistance, hybrids with species, genetic studies.
North Carolina, Willard.	do	George M. Darrow, C. F. Williams (cooperator of North Carolina station).	1929	Do.
Oregon, Corvallis	C. E. Schuster, B. S. Pickett, G. L. Rygg, G. M. Darrow.	G. F. Waldo	1928	Large-fruited, hardy, canning, and freezing varieties, hybrids with species.
Canada:				
Ottawa	William Saunders, W. T. Macoun, A. J. Logsdail, John Craig.	M. B. Davis, W. Hunter.	1873 [4]	Hardiness.
Agassiz, British Columbia.				
Vineland, Ontario	F. S. Reeves	W. J. Strong, E. F. Palmer.	1913	Disease-resistant, canning, large varieties, earliness, hardiness, yield, high flavor.
England:				
Long Ashton, Bristol		J. G. Maynard, G. T. Spinks.		Table and canning varieties.
East Malling, Kent		N. H. Grubb		Disease resistance.
Merton, John Innes Horticultural Institute.		C. D. Darlington, M. B. Crane, W. J. C. Lawrence, Faberge.	1920	Blackberry-raspberry genetics.
Sweden: Alnarp		C. G. Dahl	1930	High flavor with suckers.
Norway: Njos, Hermansverk.		P. Stedje	1930	
Switzerland: Wadenswil Experiment Station.				

[1] Recently.
Or earlier.
[3] About.
[4] Official since 1887.

TABLE 5.—*Raspberry varieties originated by public agencies*

Location	Variety	Year introduced	Parentage	Superior qualities
State stations:				
Alaska, Sitka	Bensonberry	1920	Cuthbert × Salmonberry.	Perennial canes, suckers, light-yellow fruit.
Minnesota, St. Paul	Latham	1914	King × Loudon	Hardy, productive, large, attractive, late, firm.
	Chief	1930	Latham Selfed	Cold-resistant, high flavor, early, productive, vigorous, bright red.
North Carolina, Raleigh.	Dixie	1936–37	*Rubus biflorus* × Latham	Productive, disease resistant.
North Dakota, Fargo	P-117	1935	(Latham × Farmer) F_2	Cold-, drought-, and red-spider resistant, purple.
New York, Geneva	Red:			
	Donboro	1908	Loudon × Marlboro	Bright red.
	Louboro	1908	do	
	Marlative	1908	Marlboro × Superlative	Attractive.
	Marldon	1908	Marlboro × Loudon	
	June	1909	Loudon × Marlboro	Bright red, very early, productive.
	Ontario	1918	N. Y. 94 (Superlative × Loudon) selfed.	Very early, bright, productive.
	Cayuga	1922	June × Cuthbert	Earlier, firmer, brighter than Cuthbert.
	Owasco	1922	do	Large, high flavor.
	Seneca	1922	do	Late, high flavor.
	Newburgh	1929	Newman × Herbert	Very large, firm, productive, mosaic-escaping.
	Monroe	1932	Newman × Cuthbert	Midseason, firm, good.
	Ulster	1933	Herbert × June	Early, large, productive.
	Taylor	1935	Newman × Lloyd George	Large, late, firm, bright-red, high flavor.
	Indian Summer	1936	1950 (Empire × Herbert) × Lloyd George.	Fall fruiting, large.
	Marcy	1936	Lloyd George × Newman.	Very large, good flavor, mosaic-escaping.
	Black.			
	Dundee	1927	Smith No. 1 × Palmer	Large, attractive, high flavor.
	Naples	1931	Honeysweet × Rachel	Late, firm.
	Bristol	1934	Watson Prolific × Honeysweet.	Early, firm, high flavor.
	Evans	1935	do	Early, attractive, high flavor.
	Purple:			
	Brant	1926	Smith No. 1 × June	Large, firm, attractive.
	Webster	1926	Smith No. 1 × unknown purple.	Firm, productive.
	Sodus	1935	Dundee × Newburgh	Firm, large, productive, attractive.
South Dakota, Brookings.	Sunbeam	1906	Shaffer × Cavalier wild	Hardy.
	Ohta	1912	Cavalier wild × Minnetonka.	Late, firm.
	Fewthorn	1922	Minnetonka × Black Hills wild.	Few prickles, firm.
	Moonbeam	1922	(Cavalier wild × Black Hills wild) × Shaffer	Late, firm.
	Smoothcane	1922	Black Hills wild × Minnetonka.	Firm, thornless.
	Spineless	1922	Cavalier wild × Loudon	No prickles.
	Starlight	1922	Cavalier wild × Minnetonka.	right, large.
	Twilight	1922	Seedling of wild or hybrid with cultivated.	Light red.
U. S. D. A. station:				
Maryland, Glenn Dale.	Van Fleet	1924	*Rubus kuntzeanus* × Cuthbert.	Vigorous, disease-resistant, hardy in South.
	Potomac	1932	Farmer × Newman	Disease-resistant (resistant to streak virus), purple, hardy, jam and canning.
Canada:				
Ottawa	Saunders	1880	Philadelphia × McCormick.	Dark red.
	Sarah	1893	Seedling of Shaffer	Suckers, very late, firm, high flavor.
	Carleton	1894	Seedling of Biggar	Early.
	Citizen	1894	Gregg × Cuthbert	Purple, suckers.
	Count	1894	Seedling of Biggar	Early, vigorous, large, bright-red, firm.

TABLE 5.—*Raspberry varieties originated by public agencies*—Continued

Location	Variety	Year introduced	Parentage	Superior qualities
Canada—Continued.				
Ottawa	Craig	1894	Unknown	Midseason.
	Duncan	1894	Gregg × Cuthbert	Purple, suckers and tips, late, vigorous, firm.
	Empire	1894	Seedling of Biggar	Early, vigorous, firm.
	Garfield	1894	do	Firm.
	Garnet	1894	Seedling of Philadelphia.	Purple, suckers, late, vigorous.
	Lady Ann	1894	Seedling of Biggar	Yellow.
	Mary	1894	Unknown	
	Muriel	1894	Seedling of Biggar	Vigorous, early.
	Sharpe	1894	do	Early, firm, vigorous.
	Sir John	1894	do	Early, bright-red.
	Trusty	1894	Unknown	Late, firm, vigorous.
	Deacon	1900		Deep red.
	Henry	1900		Early, hardy, productive.
	Nelson	1900		Deep red.
	Lorne	1900		Early.
	Shinn	1900		Firm, productive.
	Brighton	1900	Unknown	Hardy, deep red, very early.
	Percy	1900	Gregg × Cuthbert	Purple, firm.
Vineland, Ontario	Viking	1924	Cuthbert × Marlboro	Vigorous, high flavor, productive, firm.
Union of Soviet Socialist Republics:				
Michurin Institute	Tekhas Productivnaia.	1905[1]	Seedling of Logan	Hardy, tip-rooting.

[1] Selected.

TABLE 6.—*Private raspberry breeders*

Name and location	Varieties	Year introduced	Cross	Desirable qualities
United States:				
W. E. Lammertz, Armstrong Nurseries, Ontario, Calif.				
H. Rockhill, Conrad, Iowa.	3 being propagated.		Latham × Older	Purple, hardy, firm.
H. M. Butterfield, Berkeley, Calif.				
A. C. Dike, Bristol, Vt.	Dike	1933	June × Latham	Heavy bearer, resistant to mosaic.
Canada:				
C. P. Newman, Ville La Salle, Quebec.	Newman	1919	From mixed seed of Herbert, King, Loudon, Cuthbert, and Eaton.	Hardy, productive, firm, mosaic-resistant.
	Newman 20	1915	Seedling of Eaton	Large, late, firm.
George Adams, Smithville, Ontario.	Adams 87			Hardy, bright red, does not turn dark.
	Adams 101			Firm, propagates by tip-rooting.
England:				
Laxton Bros., Bedford.	Bountiful	1917		Large, sweet.
	Prolific	1922		Productive.
	Renown	1925	Abundance × Superlative.	Bright, red, sweet.
	Yellow Hammer	1925		
	Reward	1935		
George Pyne, Topham, Devon.	Devon	1904	Seedling	Vigorous, large clusters; does not turn dark.
	Pynes Royal	1913	Seedling raised in 1907	Largest English, sweet.
	Red Cross	1917	Seedling	Tart, large, early.
	Park Lane	1922	do	High flavor.
	Mayfair	1929	Seedling of Park Lane	Do.
	Better-Late	1931	Blackberry-raspberry × raspberry.	Jam variety, very late.
	Imperial	1935	Seedling of Royal	Larger than Royal, conical, very vigorous, productive.

Source of Superior Qualities in Raspberries

Plant Characters

Hardy against cold. Ohta, Latham, Chief, Potomac (purple), Sarah, Starlight, Sunbeam, Newman, Adams 87, Newburgh, King, London, N. Y. 3024 (June × Brighton), P 117 (Latham × Farmer F_2 of North Dakota), Heath (black), Tekhas (in Russia).

Resistant to heat. Van Fleet, Dixie, Ranere.

Resistant to drought. Sodus, Latham, Marcy.

Resistant to leaf spot. Van Fleet, Ranere, U. S. D. A. No. 9 (Latham × Ranere), Dixie, Potomac, Evans; Pynes Royal and Baths Perfection (in England); *Rubus biflorus*, *R. innominatus*, *R. inopertus*, *R. kuntzeanus*, *R. parvifolius*, *R. phoenicolasius*.

Resistant to anthracnose. Van Fleet, *Rubus coreanus*, *R. kuntzeanus*, *R. biflorus*, *R. innominatus*, *R. niveus*, North Carolina R–14, Quillen and Naples (black), Potomac (purple), Ranere.

Resistant to yellow rust (*Phragmidium rubi-idaei*). Black raspberries (*Rubus occidentalis* and *R. leucodermis*) immune; highly resistant reds are Lloyd George, Owasco, Seneca, Antwerp, Ranere (not in California), Cayuga, Herbert, Chief.

Resistant to leaf rust (late raspberry rust). Hailsham red; all black raspberries are very resistant.

Resistant to spur blight. Columbian, Newman, and Marcy red show some resistance; probably all black varieties are resistant.

Resistant to streak. Potomac and all red varieties.

Immune to leaf curl. All purples and Farmer and New Logan blacks.

Resistant to green mottled mosaic. Latham, Chief, Ranere.

Escaping green mottled mosaic. Lloyd George, Herbert, Newman, Marcy, Indian Summer, Ranere, Potomac.

Resistant to mosaic in England. MacLaren, Baumforth A, Red Antwerp B.

Resistant to crown gall. Surprise (of California).

Resistant to verticillium wilt. Syracuse, Cuthbert, Ohta, Antwerp, Marlboro, Cayuga, Owasco, Seneca; Superlative and Black Antwerp A (in Europe); *Rubus biflorus*.

Resistant to aphid (*Amphorophora rubi*). Lloyd George, Herbert, Newburgh, Newman.

Everbearing. Ranere, La France, Erskin Park (summer bearing), Lloyd George (fall fruiting in the Northwest), Indian Summer, Hailsham (in England), November Abundance.

Fruit Characters

Early ripening. U. S. D. A. No. 0 (Latham × Ranere), Ranere, June, Chief Ohta, Marlboro, N. Y. 3024, Red Cross (in England); black varieties, Shuttleworth, Kansas, Bristol, Evans.

Late ripening. Van Fleet, Latham, Newman, Taylor, Cuthbert, N. Y. 3041; black variety, Rachel.

Firm. Potomac, Newman, U. S. D. A. No. 9 (Latham × Ranere), Newburgh, Latham, Ranere (in California); Baumforth seedling B, Burnett Holm, Penville Champion, and Pynes Royal (in England).

Large. Imperial, Pynes Royal, Lloyd George, Preussen (in England); Marcy, Newburgh, Taylor, Latham; Sodus (purple); Bristol, Dundee, and Cumberland (black).

Preserving. Cuthbert, Potomac, Columbian, Lloyd George.

Canning. Washington No. 89 (Cuthbert × Lloyd George); Cuthbert, Potomac, Royal, Sodus (purple).

Freezing. Latham, Chief, Viking (in the East); Washington No. 16, Lloyd George, Cuthbert, Viking, and Newburgh (in the West).

Small seed. Van Fleet, Lloyd George.

Bright red. U. S. D. A. No. 9 (Latham × Ranere), Washington No. 76 (Lloyd George × Cuthbert), Ohta, Ranere, Chief, June, Newman, Taylor, Adams 87, and Latham; Newburgh (in Oregon); Preussen (in England).

Do not turn dark. U. S. D. A. No. 9. Newburgh, Taylor, Viking, June, Adams 87; in England, Burnett Holm, Northward, Preussen, Baumforth B, Hornet A.

Excellent flavor. Cuthbert, Viking, Cayuga, Chief, Taylor; black varieties, Bristol, Evans, Honeysweet, Cumberland; in England, Norwich Wonder A, Preussen, Baumforth B, Hornet A, Pyres Royal, Park Lane.

Productiveness. Latham, Viking, Newburgh, June, Taylor, Marcy, and Bristol (reds); Cumberland (black); Potomac and Sodus (purple); in England, Lloyd George and Baumforth A.

IMPROVEMENT OF CURRANTS AND GOOSEBERRIES

GEORGE M. DARROW, Senior Pomologist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

CURRANTS and gooseberries are closely related bush fruits that are far more extensively raised and prized in Europe than in the United States. They were formerly grouped into a single genus, *Ribes*, but now the gooseberries are generally placed in a separate genus, *Grossularia*. Though hybrids have been made between currants and gooseberries, only sterile seedlings have so far been raised.

MATERIAL FOR CURRANT BREEDING

THE red currant seems to have been cultivated first some time before 1600 in the Netherlands, Denmark, and around the Baltic Sea. According to Hedrick,[1] in 1665 Rea mentioned three red currant varieties, one white, and one small black. Currant bushes were ordered for the Massachusetts colony in 1629; thus they were early brought to North America. By 1826 about 20 cultivated varieties were known in England, a good many of which were brought to the United States soon after their introduction. Most of the currant industry was based on European varieties until about 1890. Fay, a seedling raised by L. Fay, Portland, N. Y., in 1868, was introduced in 1880; Wilder, a seedling of Versailles, was raised by E. Y. Teas, Irvington, Ind., about 1877; Red Cross and Diploma both originated from a cross between Cherry and White Grape made in 1885 by J. Moore, Attica, N. Y.; and Perfection originated in 1887 from a cross of Fay × White Grape made by C. G. Hooker, Rochester, N. Y. These five varieties quickly became important and constitute possibly 85 percent of the total present acreage. London Market and Victoria, the other principal varieties, are old European sorts. Thus the currant industry in the United States is based largely on varieties originated by American breeders.

The European black currant is extensively cultivated in Europe and to a lesser extent in Canada, but it has been found to be by far the most susceptible host for the white-pine blister rust fungus, and the United States Department of Agriculture advises against its cultivation in States where white pines are important forest trees.

The American black currant (fig. 1) is a much less susceptible alternate host for the blister rust fungus than the European black currant. Though cultivated as a garden crop, there is probably very little commercial acreage of this fruit. The best-known variety is the

---

[1] HEDRICK, U. P., assisted by HOWE, G. H., TAYLOR, O. M., BERGER, A., SLATE, G. L., and EINSET, O. THE SMALL FRUITS OF NEW YORK. 614 pp., illus. Albany. (N. Y. (State) Dept. Farms and Markets Ann. Rept. (1924-25) 33, pt. 2.)

Crandall, which has large berries. It grows well in the prairie regions with hot summers, but its berries ripen so unevenly that they must be picked singly. N. E. Hansen selected and introduced four American black varieties—the Tonah, Atta, Mato, and Wanka—in 1925. These bear fruit of larger size than the ordinary wild black currant.

In 1923 Thayer's work on the red and the white currant was published.[2] This aided greatly in identifying varieties and classifying

Figure 1.—The American golden or black currant. An extremely hardy and drought-resistant native currant that is a much less receptive host of the white-pine blister rust than the European black currant.

them as to their botanical origin. In 1924 Berger[3] covered species and varieties of both currants and gooseberries, and his work is very helpful in studying the group. Hedrick and his associates[4] also described the species and varieties and gave colored plates of many of the more important types.

Relation of Currants and Gooseberries to White-Pine Blister Rust

After the white-pine blister rust epidemic had shown this disease to be a serious menace to white pines in the United States, eradication of currants and gooseberries, the alternate hosts of the blister rust

[2] Thayer, P. The red and white currants. Ohio Agr. Expt Sta. Bull 371, pp 307-394, illus. 1923.
[3] Berger, A. A taxonomic review of currants and gooseberries. N. Y. Agr. Expt Sta. Tech. Bull. 109, 118 pp., illus. 1924.
[4] Hedrick, U. P., assisted by Howe, G. H., Taylor, O. M., Berger, A., Slate, G L , and Einset, O. See footnote 1.

fungus, was undertaken in sections where the white pine is important. This has restricted interest in both currants and gooseberries, and in large areas, as in New England, most of the cultivated currants and gooseberries have been eradicated. As a consequence, the acreage of currants in the United States reported for 1929 by the 1930 census, 3,574 acres, was less than half of the 7,379 acres reported in 1919. Only 1,302 acres of gooseberries were reported in 1929.

The white-pine blister rust was brought into the United States between 1898 and 1910 on white-pine planting stock imported from Europe. It is now established throughout most white-pine regions of the United States from Maine to Virginia, west to Minnesota, and in Montana, Idaho, Oregon, and Washington. Recently it has been found in northwestern California. It injures all species of the white-pine group (five-needle pines), which are among the most valuable timber trees of the northern United States, having an estimated stumpage value of about $400,000,000. The disease cannot spread from pine to pine, but only from pine to currant and gooseberry and then from these back to pine. It causes a rust on the leaves of currant and gooseberry, which may defoliate the most susceptible varieties.

Valuable white-pine forests can be protected by eradicating wild and cultivated gooseberries and currants for a distance of about 900 feet around white pines, except that black currants must be destroyed for greater distances from pines.

Currants and gooseberries differ greatly in their susceptibility to the white pine blister rust. As already noted, the common cultivated black currant—the European black currant (*Ribes nigrum* L.)—because of its high susceptibility has been the chief agency in the rapid and long-distance spread of the disease throughout the Northern States. The American black currant (*R. americanum* Mill.), the golden currants (*R. odoratum* Wendl. and *R. aureum* Pursh), and the native gooseberries (*Grossularia divaricata* (Dougl.) Spach and *G. curvata* (Small) Cov. and Britton) have seemed somewhat more sus-

AMERICAN *native species of gooseberries range from Florida far north into Canada, and some of them are resistant to high summer temperatures and to the leaf diseases that have discouraged gooseberry growing in this country. By suitable crossing, these characteristics can be combined with the great size, the fine flavor, and the beauty of varieties developed in Europe through generations of breeding, encouraged by a public that had a great fondness for this fruit. Some of the hybrids already produced in this country show what can be done in the way of improved quality and size of fruit and vigor of plant. There is no doubt that the gooseberry offers opportunities for the development of improved varieties that would be welcome additions to our gardens.*

ceptible than most cultivated varieties. Franco-German, Netherlands, and London Market currants are very resistant or nearly immune, while cultivated varieties of gooseberries are very resistant.

To protect white-pine stands, many States have established regulations governing the planting of currants and gooseberries, and some for white pines. In general, currant and gooseberry plantings are prohibited where white pine is important, and white-pine plantings where the currants and gooseberries are important. Before planting these fruits the State laws should be consulted. Summaries of the laws are given in Farmers' Bulletin 1398.[5]

G. G. Hahn, of the Division of Forest Pathology, Bureau of Plant Industry, has recently tested the Viking red currant, a variety introduced from Norway, and found it immune to blister rust. Propagating stock has been imported, and in 1935 and 1936 a large number of plants were distributed to experiment stations for testing as to its horticultural value and for breeding. Plants already fruiting in New England and New York have shown that it is of good dessert quality and desirable for jelly making. A few open-pollinated Viking seedlings, produced where cross-pollination was not eliminated, have been slightly susceptible to blister rust. The culture of the Viking in white-pine areas will depend on the policy within each State after its horticultural value and seedling susceptibility to the fungus have been fully determined.

SPECIES OF CURRANTS

Berger states that there are about 150 species of currants and gooseberries distributed all over the Northern Hemisphere, but mostly in North America, and extending along the mountains of the Americas as far south as Patagonia. At least 100 species are currants and some 50 are gooseberries. The Rocky Mountains in North America are especially rich in species. There are about 15 species of red currants, of which *Ribes sativum* Reichenb., *R. rubrum* L., *R. warscewiczii* Jancz., and *R. petraeum* Wulfen, and hybrids of them are considered important for breeders.

Ribes sativum.— A native of western Europe, frequently escaped from cultivation in North America. Leaves heart-shaped at base, five-lobed and with lobes spreading to the side, clusters 10- 20-flowered, flowers flat, greenish yellow. Chautauqua, Diploma, Red Cross, Versailles, and Wilder are typical varieties, while Cherry and Fay belong to a section of the species.

Ribes rubrum.—Northern Europe to northern east Asia. This species is more northern than *R. sativum*, from which it is most easily distinguished by its forward-pointing leaves and cup-shaped flowers. Leaves truncate or subcordate at base and lobes cupped or pointing forward, broader than long, clusters longer, flowers cup-shaped, pale green or brownish. London Market and Victoria are typical varieties. Perfection is derived from *R. rubrum* × *R. sativum*.

Ribes warscewiczii.—A very productive species of eastern Siberia, worthy of use in breeding. Leaves large, heart-shaped; clusters about 15-flowered, flowers coppery red to pale flesh-colored; fruit large, blackish purple, very acid. Near to *R. rubrum*, but flowers larger and fruit more acid.

Ribes petraeum.—Very widely distributed over Europe, northwestern Africa, and northern Asia. Leaves roundish, pubescent when young; flowers bell-shaped, green streaked with red or purple; fruit red or blackish red, more acid than *R. sativum* or *R. rubrum*. Growth starts late in spring. Prince Albert is derived from *R. petraeum* × *R. rubrum*, and Gondouin from *R. petraeum* × *R. sativum*.

[5] DARROW, G. M., and DETWILER, S. B. CURRANTS AND GOOSEBERRIES; THEIR CULTURE AND RELATION TO WHITE-PINE BLISTER RUST. U. S. Dept. Agr. Farmers' Bull. 1398, 38 pp., illus. 1924.

The black currants of Europe are all derived from *Ribes nigrum*. It is more vigorous than the red currant species, and the whole plant has a characteristic aroma. To many the fruit flavor is objectionable; to others highly pleasing. It is a native of Europe as far north as Scandinavia, and of northern and central Asia. An allied species, *R. ussuriense* Janc , is native to eastern Manchuria, but the plant has a camphorous aroma and the fruit has no odor. The American black currant, *R. americanum*, has an aroma in the plant and fruit similar to that of *R. nigrum*. It ranges from New Mexico to Virginia northward into Canada. One variety, Sweet Fruited Missouri, has been in cultivation, though the fruit is sometimes gathered in the wild. It is not especially promising.

The golden currants, native in central and northwestern United States to northern Mexico, are often known as American black currants Yellow- or golden-fruited forms are common. The most common variety is the Crandall, with rather large fruit. There are several species, but all are close to *Ribes odoratum*, to which the Crandall belongs.

There are many ornamental species of currants in the Rocky Mountain region, but they are mostly of little value for their fruit.

MATERIAL FOR GOOSEBERRY BREEDING

THE gooseberry seems to have come into cultivation at about the same time as the currant. According to Hedrick, it was grown in English gardens before 1600. By 1629 there were 3 red varieties, a blue, and a green variety described; by 1778, 24 varieties were described; by 1825, 185 kinds were listed; and in 1831 a list of 722 varieties was published. The great development in the size of the European gooseberry was in part due to the high esteem in which it is held in England, and to the shows held there. For example, 171 gooseberry shows were held in England in 1845. Prizes were given for the heaviest fruits, and in 1852 a berry of the London variety was shown that weighed 7 grams (about one-fourth ounce), or seven to eight times the weight of the wild fruit.

In North America the European gooseberries were attacked by mildew, and gooseberries were little grown until after the Houghton was originated from seed planted in 1833 by A. Houghton, Lynn, Mass. Houghton was from a cross of the European with an American variety, and from seed of it Charles Downing, Newburgh, N. Y., raised the Downing about 1855 (fig. 2, *C*). The gooseberry industry of the United States was largely based on these two varieties until about 1900, or until after the use of fungicides became common so that mildew could be controlled on varieties from Europe or of European parentage, such as Chautauqua and Industry. Since 1900 several varieties have become prominent: Oregon (Oregon Champion), a cross between Crown Bob and Houghton, raised about 1860 by P. Prettyman in Oregon; Pearl, a cross of Downing × Red Warrington, originated by William Saunders, London, Ontario, and introduced in 1888; Red Jacket (Houghton × Red Warrington), also originated by Saunders and introduced about 1890; Carrie, a seedling of Houghton, raised by W. Elliot, Minneapolis, Minn., and introduced in 1905;

Poorman, a seedling raised by W. H. Craighead, Brigham, Utah, and introduced in 1896; and Como (Pearl × Columbus), originated at the Minnesota Agricultural Experiment Station and introduced in 1922. Of these varieties, Poorman (fig. 2, *B*) has the best appearance and

Figure 2.—*A*, Columbus, a large European gooseberry; *B*, Poorman gooseberry, the largest of the hybrids between American and European varieties; *C*, Downing, a hybrid that has long been the most important American gooseberry.

is excellent in quality, comparing favorably with the best European sorts. Though considered a cross between Downing and Houghton, it may possibly have been a cross with one of the Rocky Mountain species.

Species of Gooseberries

The gooseberries of Europe are derived from the one species *Grossularia reclinata* (L.) Mill., which ranges from northern Africa through Europe from Spain to the Caucasus, north to Scandinavia. *G. uva-crispa* (L.) Mill., a native of central Europe, is said to be more drought-resistant, with very sweet late fruits. It starts growth about 2 weeks later than the species. Berger considers that the Houghton was derived from a cross of this form of the European gooseberry with *G. hirtella*. Most of the rest of the species of gooseberries are natives of North America, and several are promising for breeders.

Grossularia cynosbati (L.) Mill.—Native from North Carolina to Missouri, north to Manitoba and New Brunswick, Berry prickly, wine red, with a rather thick skin. Bush to 4.5 feet high; common in woods and rocky places.

Grossularia missouriensis (Nutt.) Cov. and Britton.—Native from Tennessee to Kansas, north to Minnesota and South Dakota. Berry not prickly, purplish. Bush to 6 feet high. The Glenndale, derived from this crossed with European varieties, is very vigorous and productive and stands the hot summers better than other gooseberries.

Grossularia divaricata (Dougl.) Spach, the coast gooseberry.—Native from central California to British Columbia. Berry small, dark purple or black, not prickly. Bush 6 to 10 feet. Trebla, a variety propagated by A. F. Etter, is supposed to have been derived from a cross of this species with cultivated varieties.

Grossularia hirtella (Michx.) Spach.—Native from West Virginia to South Dakota and north to Newfoundland and Manitoba. Berry purple or black, not prickly. Bush to 3.5 feet. Houghton, Downing, Pearl, Carrie, Oregon, and other varieties are considered to have been derived from crosses of this species with the European varieties. It has given mildew resistance to American varieties.

Grossularia oxycanthoides (L.) Mill.—Native from Michigan to North Dakota, north to Newfoundland and the Yukon. Berry smooth, purple, sweet, good; bush low, spreading; branches bristly. A hardy, far-northern species.

Grossularia nivea (Lindl.) Spach, the Snake River gooseberry.—Native to northern Nevada, Idaho, eastern Washington, and Oregon. Berries smooth, bluish black, very good; bush 5 to 10 feet high; somewhat similar to *G. missouriensis*.

Grossularia curvata (Small) Cov. and Britton.—Native from Georgia to Texas. Berry green to purplish, smooth; bush low, spreading; branches arching. Promising for breeding, because native to the South.

Grossularia echinella Cov.—Native to northern Florida. Berry very prickly, large, green, bush spreading. Promising for breeding because native to the South and because of its large fruits.

Grossularia rotundifolia (Michx.) Cov. and Britton.—Native from North Carolina to Massachusetts in rocky places in woods. Berries smooth, purplish; bush with slender arching branches.

Grossularia irrigua (Dougl.) Cov. and Britton, the inland black gooseberry.—Native to western Montana and eastern Oregon, north to British Columbia. Berries smooth, purple or black; bush 3 to 10 feet high.

Besides these species there are others in the western United States that may be of value. Thus *Grossularia lobbii* (A. Gray) Cov. and Britton, *G. pinetorum* (Greene) Cov. and Britton, *G. sericea* (Eastwood) Cov. and Britton, and *G. marshallii* (Greene) Cov. and Britton have large fruits but with prickles or glandular bristles. Of the species listed above, *G. nivea* is possibly one of the most promising for breeding.

SYSTEMATIC BREEDING WORK WITH CURRANTS AND GOOSEBERRIES

Very little systematic breeding work has been done with currants and gooseberries. The fact that nearly all the red currant varieties grown in this country originated here indicates the possibilities for

improvement of this fruit, particularly in breeding for resistance to leaf diseases; and this is borne out by the more recent red currant work at the Minnesota Agricultural Experiment Station. Varieties of red currants resistant to cane blight (*Botryosphaeria ribis* Gross. and Dug.) and with foliage resistant to leaf spot (*Septoria ribis* Desm.) are needed to make the currant a useful garden and commercial fruit in many sections where it is now difficult to grow. The hardiness, drought resistance, and great vigor of the American black currants (golden currants) make this group also promising. Selections of these currants are needed that mature many or all berries on a cluster, so as to reduce the cost of harvesting.

Probably the greatest opportunity, however, is in gooseberry breeding. The chief need is for fine-flavored, attractive-fruited varieties that are resistant to leaf spot, to high summer temperatures, and to mildew (*Sphaerotheca mors-uvae* (Schw.) Berk. and Curt.). Such southern native species as *Grossularia echinella* and *G. curvata* endure high summer temperatures and are resistant to mildew. Some resistance to leaf spot seems to be shown by *G. missouriensis* and probably certain other native species. European gooseberries cross readily with American species, and the productiveness and vigor of the hybrids have indicated how promising this line of work might be. Poorman, though not so large as many of the European gooseberries, is larger than the other hybrids and has greater beauty and better flavor when ripe than European varieties now grown in this country. The Glenndale has greater vigor than most other hybrids and far greater vigor than the European sorts. American native species range from Florida far north into Canada; and varieties with the size of the European, the quality and beauty of Poorman, the vigor of Glenndale, and the range of American species would be welcome additions to our garden fruits.

Work of Experiment Stations With Currants and Gooseberries[6]

In South Dakota, crosses were made between the native wild gooseberry of South Dakota (*Grossularia missouriensis* (Nutt.) Cov. and Britton) and the large-fruited European varieties. The first hybrid variety to be introduced was Sunset in 1924, followed in 1925 by Kabu, Kaduza, Kana, Kanga, Kapoza, Kataga, Kawauka, Kazouta, Kaza, and Kopa. In addition, the station has grown many thousands of seedlings of the native gooseberry, selecting the best for a new generation. Seedlings of the native wild gooseberry were first introduced in 1921, and up to 1927 eight generations of seedlings had been raised.

Similar work in growing thousands of seedlings of the wild black currant resulted in the selection in 1923 of large-fruited seedlings. Four were named and introduced in 1925—Tonah, Atta, Mato, and Wanka. In addition the Siberian black currant, collected by Hansen in 1897 in Siberia, was introduced in 1910.

In North Dakota, breeding with the gooseberry was begun in 1920, the native wild gooseberry (*Grossularia missouriensis*) being crossed

---

[6] A. S. Colby (Illinois), G. L. Slate (New York), A. N. Wilcox (Minnesota), and A. F. Yeager (South Dakota) kindly furnished details of the breeding work with currants and gooseberries at their experiment stations.

with Oregon Champion, Transparent, Houghton, Downing, Copland, Josselyn, and Carrie. The best combination was with the Oregon Champion. In 1932 three of the seedlings were named and introduced—the Pixwell, Abundance, and Perry. Pixwell is considered especially good for jelly, preserves, and sauce. *G. setosa* Lindl., another wild gooseberry from North Dakota, was also crossed with Oregon Champion, and though the first hybrid generation was not particularly promising, the second showed better seedlings. A. F. Yeager, in charge, noted that red color of fruit was dominant over green, smooth fruit over downy, and long pedicel and peduncle over short. He also found a dwarf plant type in Oregon Champion crosses and observed that a light-green color of unripe fruit was apparently, dominant over dark-green color. He is studying inheritance of thorns, winter hardiness, and drought and heat resistance.

In New York gooseberry breeding was begun at the New York (State) Agricultural Experiment Station at Geneva in 1892 and has been continued at intervals since. The Fredonia, introduced in 1926, is the only variety resulting from the work. It is a seedling of Crown Bob and is large, late, and productive for an English type. Among the varieties crossed are America, Boskoop, Black Champion, Chautauqua, Crandall, Downing, Honing Fruheste, High Sheriff, Houghton, May Duke, Lancashire Lad, Pale Red, Wellington Glory, Whitesmith, and Victoria. This station maintains a very large collection of species and varieties.

A small number of currant crosses have been made, but no varieties have been introduced. A large collection of currant varieties and species is also maintained. George L. Slate reported that crosses have been made as follows:

Fay × Missouri Sweet Fruited.
Fay × Crandall.
White Transparent × Crandall.
Cherry × Crandall.
Black Naples × White Transparent.
White Transparent × Black Naples.
Diploma × Black Naples.
Lee (black) × Mountain (gooseberry).
Black Naples × Downing.
Boskoop (black) × Poorman.
Lee × Poorman.
Boskoop × *Ribes sanguineum.*
Chautauqua × *Grossularia echinella.*

In Minnesota the breeding of gooseberries was begun in 1909 and has been continued since. Carrie, Chautauqua, Columbus (fig. 2, *A*), Houghton, Josselyn, and Pearl have been intercrossed and crossed with selections of wild species. *Ribes hirtella* Spach has been used to obtain thornlessness. Como, a cross of Pearl × Columbus, was introduced in 1922. It has resistance to sun scald and to disease and is productive. It is especially good in cooking qualities.

The raising of seedling currants was begun in 1912 and has been continued to the present. No crossing has been done. The Red Lake variety was introduced in 1933, being selected for the large size of the berry and of the cluster and for its productiveness. It is succeeding well in New Jersey and in other Eastern States.

In Illinois the work with gooseberries was begun in 1924 with the objective of obtaining greater production, larger size, higher flavor,

fewer thorns, and disease-resistant foliage. Poorman, Spinefree, Chautauqua, Carrie, Glenndale, and Transparent have been intercrossed, and over 2,000 seedlings are under test. Papers by Colby,[7] in charge, indicate the accomplishments.

Work of the United States Department of Agriculture with Currants and Gooseberries

The work at the United States Northern Great Plains Field Station at Mandan, N. Dak., under W. P. Baird, has consisted largely in raising seedlings and making selections of the native hardy, drought-resistant, productive wild black currant *Ribes odoratum*. In 1924, selections of this currant were crossed, and about 50 selections have been made. Baird has noted that black fruit is dominant over yellow and red and that a round shape is dominant over oblong. Some gooseberry and red currant breeding has been done. The drought of 1936 killed most of the gooseberry and red currant selections, but the black currants withstood it.

At Corvallis, Oreg., a collection of the best-fruited forms of the native species of currants and gooseberries was made by L. N. Goodding, and hybridizing was begun by George F. Waldo.

At Washington, D. C., crosses have been made in recent years by F. V. Coville and O. M. Freeman between *Grossularia echinella*, a gooseberry species native to Florida, and cultivated varieties. Several selections were made, and the second hybrid generation is being raised at Beltsville, Md.

In 1932 the Glenndale gooseberry was introduced. This originated as a seedling raised by the late W. Van Fleet probably about 1905, before he joined the Department of Agriculture, from a cross of ((*G. missouriensis* × Red Warrington) × Triumph) × Keepsake. It is a very rank-growing variety, which succeeds from Maryland and Virginia to Kansas, at the southern limit of gooseberry growing.

Currant and Gooseberry Breeding in Foreign Countries

The Dominion station at Ottawa, Canada, has introduced at least four varieties of gooseberries—Charles, Silvia, Mabel, and Spinefree, the last-named being a cross of a second-generation thornless wild with Mabel. It is described as of good flavor, thick-skinned, bright red, free of spines, upright, vigorous, free of mildew, and resistant to leaf spot.

This station also introduced the following 12 black currants originated by William Saunders before he became director in 1887: Climax, Clipper, Eclipse, Ethel, Kerry, Magnus, Ogden, Ontario, Saunders, Success, Topsy, and Winona. Of these, Kerry, Clipper, Eclipse, and Climax are recommended varieties in Canada.

At the East Malling Horticultural Research Station in England, the production of improved varieties of red and black currants is a breeding project. The use of X-rays to induce mutations, and a study of inheritance in black currants, are two lines of research now under way.

---

[7]Colby, A. S. SIZE INHERITANCE IN GOOSEBERRY FRUITS. Amer. Soc. Hort. Sci Proc. (1933) 30: 105-107. 1934.

——— INHERITANCE OF GOOSEBERRY LEAF INFECTION. Amer. Soc. Hort. Sci. Proc. (1934) 32: 397-399. 1935.

At the University of Bristol production of heavy-cropping varieties of black currants is one objective, and two varieties have been named and introduced. At times some gooseberry breeding for mildew resistance has been carried on at this station.

Laxton Bros., of Bedford, England, have done much breeding work with black currants and gooseberries, and some with red currants. They have introduced the following red currants and gooseberries:

TABLE 1.—*Currants and gooseberries introduced by Laxton Bros., of England*

Variety	Year introduced	Parentage	Superior qualities
Red currants			
Perfection	1909		Long clusters, sweet, large
Laxton's No. 1	1925		Vigorous, productive
Gooseberries			
Bedford Yellow	1915	Gold Drop × Drill	Golden yellow, high flavor, large
Amber	1916	Wonderful × Lancaster Lad	Amber color, high flavor
Bedford Red	1922	Crown Bob × Langley Green	Red, productive
Green Gem	1922	Drill × Whitesmith	Yellowish green, high flavor
Emerald	1925	Drill × Crown Bob	Early, green, productive
Golden Ball	1928	Drill × Whitesmith	Yellow, high flavor
Rearguard	1928	Wonderful × Lancaster Lad	Very late, firm

In Sweden, C. G. Dahl, in charge of the gooseberry breeding at Alnarp, reported that breeding was begun in 1911 to obtain mildew-free varieties. *Grossularia divaricata* (Dougl.) Cov. and Britton and *G. nivea* (Lindl.) Spach were crossed with European varieties. Some 1,000 plants were raised, and one variety, Scania, has been introduced. It is free from mildew and produces a strong plant and large fruit. A second variety, a second-generation hybrid from *S. nivea* × a European variety, is being distributed under the name Centum. It is also free from mildew, with fruit like Downing, of fine flavor.

In the Union of Soviet Socialist Republics, I. V. Michurin originated one gooseberry variety, Shtambooii, which was reported to be resistant to mildew.

SOME UNUSUAL OPPORTUNITIES IN PLANT BREEDING

GEORGE M. DARROW, Senior Pomologist,
GUY E. YERKES, Horticulturist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry

OPPORTUNITIES for the development of new and improved plants by breeding are by no means limited to those now grown in home or commercial gardens. All our present cultivated plants, it must be remembered, have been derived from wild plants. Those that were most outstandingly useful or most readily adaptable to cultivation, man took from forest and field and grew in his own dooryard. Others he left in their wild state, for one reason or another, though he continued to use their products. One of the plants left wild until very recently was the blueberry. The work of the late Frederick V. Coville, described elsewhere in this Yearbook, shows how modern knowledge and modern technique, applied to suitable wild material, can change and improve it enormously for human uses. Not all neglected wild plants, undoubtedly, would produce such splendid results as the blueberry under Coville's handling, but the achievement suggests that there is a wealth of material not yet touched, awaiting merely the right imagination and the right opportunity for the breeder to transform it in greater or less degree.

Some of the native wild plants and introductions from foreign countries need only careful selection of superior strains to increase their usefulness. In other cases a planned program of breeding is necessary, including crosses with types already in cultivation. It must be recognized that hybrids between distinct species are made with considerable difficulty in most cases, and only rarely are they directly valuable in a horticultural way. However, occasionally valuable things do come from such distant crosses, and the only way to find them is to make the attempt.

PLANTS THAT AWAIT THE BREEDER'S ATTENTION

SOME of this material may be mentioned at random here. In the Northeastern States some people use milkweed like asparagus and also make soup of it. If varieties with many short internodes on their underground stems could be located and improved by breeding, they might be a welcome addition to the perennial vegetable garden. Different colored varieties of the butterfly milkweed might be selected and bred as ornamentals. Strains of the hard or sugar maple that came true to various autumn leaf colors would be desirable additions to our list of shade trees, and others might be found with unusually high sugar content in the sap, to be used in the sugar bush. Search

might reveal strains of longleaf pine trees having high turpentine yield. Trees of upright narrow form have special value in landscape use, especially for screens, high hedges, and narrow streets. Lombardy poplar, quite widely used for this purpose, usually proves short-lived. If more varieties of long-lived trees of this form could be developed, they would be valuable additions to our nursery products. Such forms have been propagated from American elm, several species of maple, English oak, oriental cherry, and others, but they have never been as extensively planted as this form warrants. Chinese elm apparently has received little attention from the standpoint of developing varieties of columnar or pyramidal or low-growing dense form, though such varieties would be useful, especially in sections subject to drought and other conditions adverse to some of the other trees.

Native hardy rhododendrons and azaleas are a fascinating group for breeding, with the object of developing varieties that would endure the summer heat encountered from Philadelphia southward better than present varieties, and also of increasing the winter-hardiness of some Asiatic forms, especially *Rhododendron obtusum* Planch. and allied species. Although this group of plants is rather limited in its adaptability because of soil and climatic requirements, its use is increasing very rapidly wherever any of its diverse forms can be grown well. *R. calendulaceum* Torr., the flame azalea of the southern Appalachians, owing to its hardiness and splendid range of colors, offers a good subject not only for crossing with other species but also for selecting the best specimens in the wild and propagating them as varieties.

There are many unusual or unimproved native and introduced fruits awaiting the attention of the breeder. Some of these have been studied more or less casually, but many are worthy of systematic continued study. For the Northern States there are the barberries (*Berberis* spp.); buffaloberries (*Shepherdia* spp.); cornelian-cherry (*Cornus mas* L.); elderberries (*Sambucus* spp.); hawthorns (*Crataegus* spp.); honeysuckles (*Lonicera* spp.); juneberries, known also as shadberries, shadblow, or sarvisberries (*Amelanchier* spp.); mulberries (*Morus* spp.); mountain ash (*Sorbus* spp.); wintergreen and salalberries. (*Gaultheria* spp.); and for the more southern States, elderberries, juneberries, the mayhaw (*Craetaegus aestivalis* Torr. and Gray), the species of *Eugenia*, feijoa (*Feijoa sellowiana* Berg.), the pawpaw (*Asimina triloba* L.), and the persimmon (*Diospyros virginiana* L.). The writers have been especially interested in the actinidias, the American cranberrybush, several species of *Elaeagnus*, the oriental quinces, and the Chinese bush cherries. Brief discussions of these as material for the plant breeder are given in the following pages. Some of the other fruits previously listed are just as promising, but they have not been so readily available to the writers.

ACTINIDIA

THE actinidias (known also as Chinese or Japanese gooseberries and sheep peaches) are climbing shrubs, chiefly of eastern Asia, ranging from the northern part of Japan south to the tropical islands.

Some seven species are in cultivation chiefly as ornamentals, for their beautiful foliage is remarkably free from insects and fungi. Two species, at least, are worth cultivating for their fruit, *Actinidia arguta* Miq., which is hardy in New England (fig. 1), and *A. chinensis* Planch., which is hardy north to Washington, D. C., though the growing season does not seem to be long enough at Washington to mature the fruit. In southern California very fine crops of *A. chinensis* are sometimes produced. The fruit of *A. arguta* is about an inch long, that of *A. chinensis* up to 2 inches, or about the size and shape of a medium to small hen's egg. The fruit is tart until fully ripe, when it is sweet, with a texture somewhat like that of a fresh ripe fig. It is used fresh, for jelly, and for sauce. The leaves of *A. chinensis* are relished by cats, like catnip. Michurin, the Russian plant breeder, has intro-

Figure 1.—One of the actinidias (*Actinidia arguta*) on a trellis at the Arnold Arboretum, Boston, Mass. The actinidias are potentially important food plants of the United States, just awaiting the study of a plant breeder. This species bears fruit about an inch long; but another kind, *A. chinensis*, bears fruit up to 2 inches long.

duced five varieties, Ananasia Michurin, Clara Zetkin, Pozdniaia (late), Raniaia (early), and Urezhainaia (high-yielding). The beauty of the vines, their wide climatic adaptation, their vigor, and the pleasing flavor of the fruit make them promising for the United States. They are readily propagated by softwood and hardwood cuttings and by layering. The one need is the origination of varieties regularly productive, for the seedlings now grown only rarely produce heavy crops. A single vine may produce several bushels of fruit one year and only a few fruits most years. Hybrids between *A. arguta* and *A. chinensis* were raised by David Fairchild, but the hybrids never fruited.

Figure 2.—The American cranberrybush in flower. The large white marginal flowers around each cluster are sterile. Only the small inner flowers set fruit.

AMERICAN CRANBERRYBUSH

THE fruit of the native American cranberrybush, highbush cranberry, or pembina (*Viburnum trilobum* Marsh.),[1] is used for jelly making in sections of the northern United States and Canada.[2] From the fruit is produced a jelly rich in color and in pectin but of relatively strong flavor and odor. The fruit resembles that of the cranberry in color and size, but

[1] Formerly known as *Viburnum americanum* Mill

[2] DARROW, G M VIBURNUM AMERICANUM AS A GARDEN FRUIT Amer. Soc Hort. Sci. Proc. (1923), 20 · 44–54 [1924]

——— THE AMERICAN CRANBERRYBUSH Jour Heredity 15 243–253, illus. 1924.

the plants are not related. The fruit of the American cranberrybush is borne on a high bush in clusters, like the elderberry, while the cranberry is borne on a low vine. The American cranberrybush is a close relative of the elderberry and grows to about the same height and in similar clumps with similar flowers (fig. 2). It is sufficiently hardy to grow in the colder parts of the United States. It is often confused with the European *Viburnum opulus* L., which is widely used in the United States as an ornamental, but is readily distinguished from the latter by its clear, acid fruit. The fruit of *V. opulus* is so intensely bitter as to be inedible.

In the spring of 1921 the Bureau of Plant Industry took over for 10 years a plantation of the American cranberrybush established by A. E. Morgan, formerly president of Antioch College, now chairman of the Tennessee Valley Authority, at East Lee, Mass. The plants were the best obtainable selections following a personal survey by Morgan of this fruit in the wild in New

Figure 3.—Three varieties of the American cranberrybush introduced by the United States Department of Agriculture through cooperating nurseries: _A_, Wentworth; _B_, Hahs; _C_, Andrews. The fruit is used for making jelly, which is as rich, red, and firm as that made from the currant and the cranberry.

York and New England and even in Manitoba and Saskatchewan. Fruit was obtained through correspondence from Alaska to Newfoundland.

After a study of the selections at East Lee, and of plants in the wild in various regions, three were named, propagated, and introduced—Wentworth, Hahs, and Andrews (fig. 3). Analyses for acid and pectin and jelly tests by C. A. Magoon, of the Bureau of Plant Industry, indicated that these three were superior to the other selections. They also covered a long season, Wentworth being early, Hahs midseason, and Andrews latest. Through cooperating nurseries these three varieties are now available in the trade. They are propagated by softwood and hardwood cuttings and by layering (fig. 4).

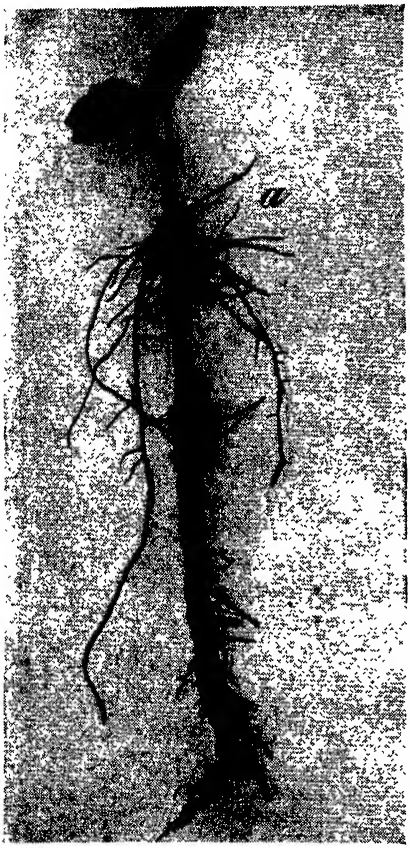

Figure 4.—Propagation of the American cranberrybush by hardwood cuttings. In this case some roots were produced along the cutting, but the largest number came from the base of the new growth (*a*).

Many northern State experiment stations have cooperated with Morgan and the United States Department of Agriculture in testing this fruit, and several are continuing their interest in it. These stations include those in Maine, New Hampshire, Massachusetts, New York, Wisconsin, Minnesota, North Dakota, Montana, and Idaho.

Besides being of value for its fruit, the American cranberrybush is a widely used ornamental, beautiful in flower and fruit, with a rich green summer foliage which becomes highly colored in fall (fig. 5).

Rehder states that there are in all about 120 species of *Viburnum*, nearly all natives of the cooler sections of the Northern Hemisphere. Many are bitter-fruited, many others are sweet-fruited, and some bear clear, acid fruit. It would seem that the viburnums have great promise for the breeder because of their value as ornamentals as well as for fruit production. Species such as *V. carlesii* Hemsl. and *V. fragrans* Bunge are delightfully fragrant, while sterile forms of *V. opulus* L. and *V. tomentosum* Thunb. are the snowballs of commerce. Valuable hybrids would probably result from crossing the Andrews, Hahs, and Wentworth with *V. carlesii*, *V. fragrans*, the evergreen *V. rhytidophyllum* Hemsl., selections of *V. lantana* L. and related sweet-fruited species, the clear acid-fruited *V. wrightii* Miq., and *V. dilatatum* Thunb.

GOUMI OR ELAEAGNUS

GOUMI is the name applied in Japan to several species of *Elaeagnus* grown chiefly for their ornamental value. One species, the cherry elaeagnus (*Elaeagnus multiflora* Thunb., fig. 6, *C*), is also of value for

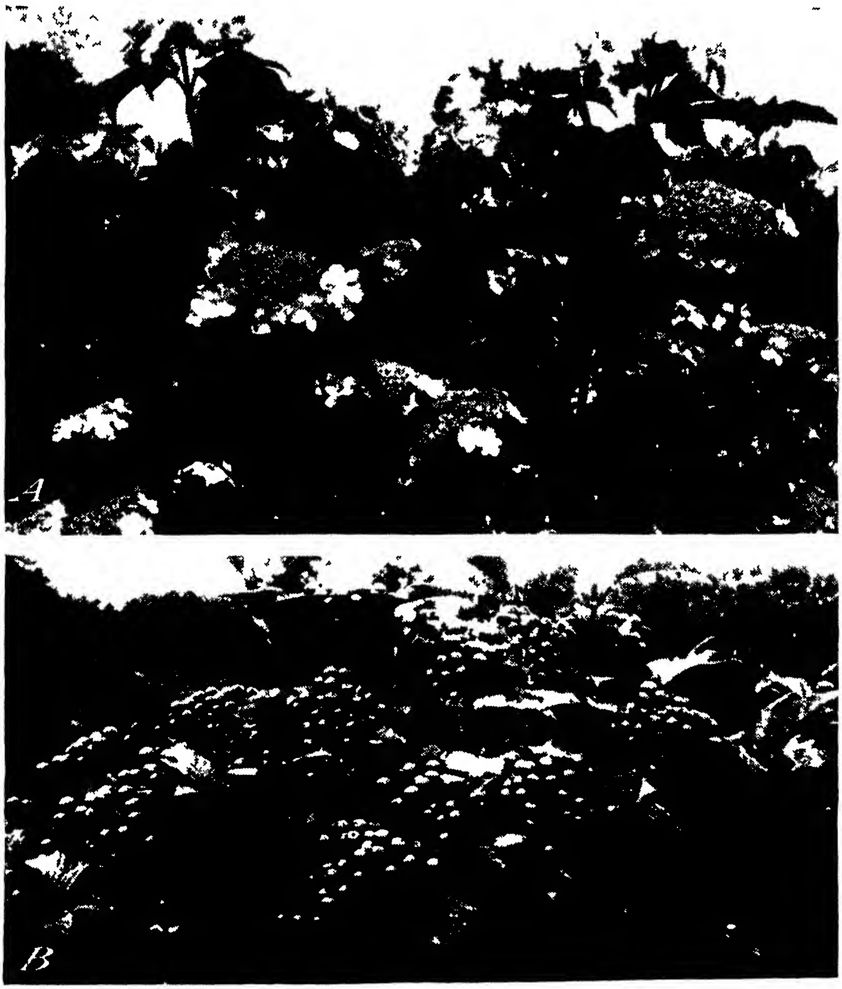

Figure 5.—The American cranberrybush is ornamental in flower (*A*) as well as in fruit (*B*). Both the white flowers and the brilliant red fruit contrast well with the foliage. It is one of the highly prized and widely used ornamentals of the northern part of the United States.

its tart fruit. Another subtropical species, *E. philippensis* Perr., called the lingaro, has produced well in southern Florida. It has edible fruit prized for use in sherbet. Still other species, such as *E. ovata* Serv. (fig. 6, *A*) and *E. umbellata* Thunb. (fig. 6, *B*), bear immense quantities of small fruit.

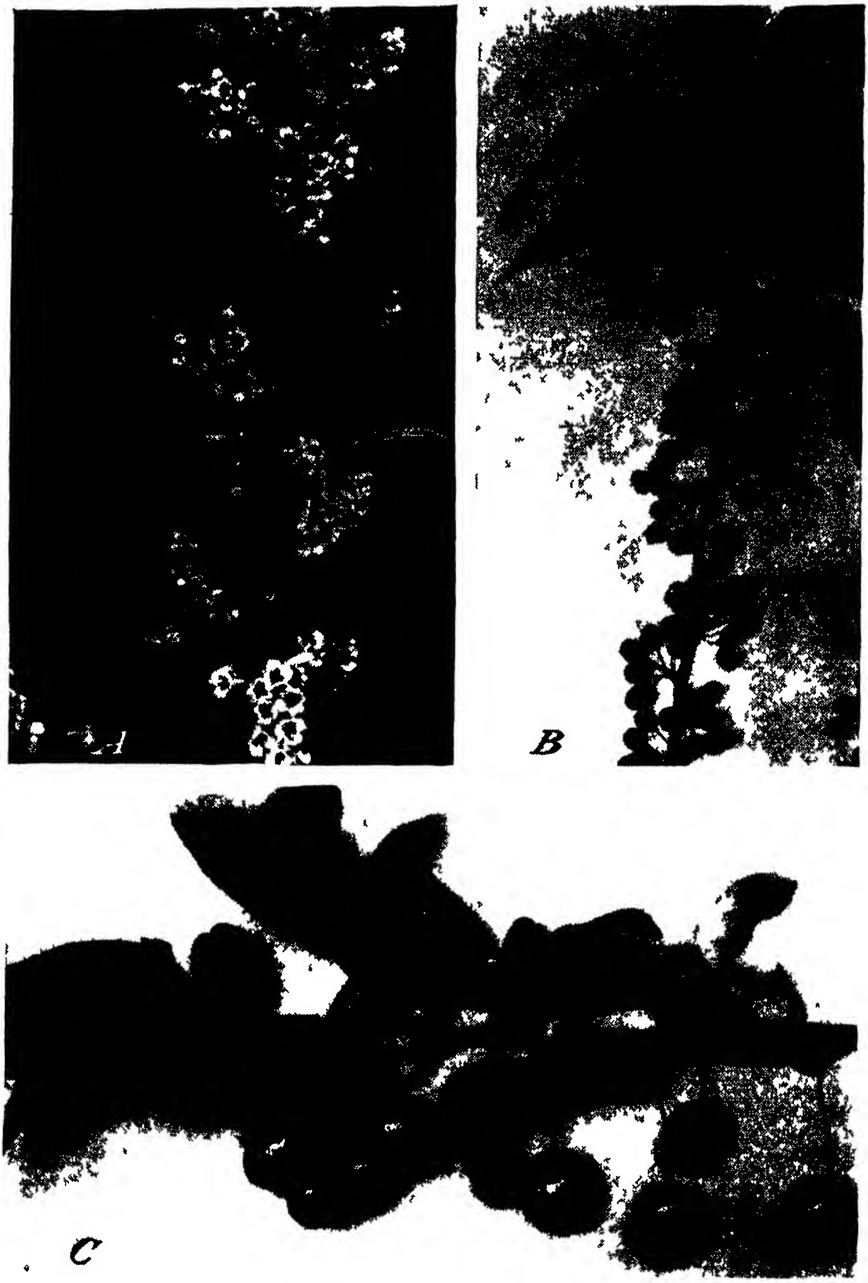

Figure 6.—Elaeagnus or goumi *A*, Flowers of *Elaeagnus ovata*, *B*, fruit of *E. umbellata*, *C*, fruit of *E. multiflora*, the largest-fruited one These hardy, drought-resistant, fruiting shrubs are valuable as ornamentals and as food for wildlife. *E. multiflora* is a valuable food plant of parts of Asia.

Though the cherry elaeagnus was introduced into this country many years ago, it has not become an important fruit even in the garden. The explanation seems to be that it has been almost entirely grown from seed. The seedlings are extremely variable, some producing very little fruit and that small and astringent, others producing abundant fruit as large as cherries and having a pleasant flavor.

Elaeagnus seems worth the attention of the breeder because the fruit is of considerable importance in parts of central Asia, the plants are very hardy and drought-resistant, the seedlings are quite variable, and there are a great many species. A breeding program might include selections of the best fruiting forms from large numbers of seedlings, and hybridizing between species such as *Elaeagnus multiflora*, *E. ovata*, *E. umbellata*, and *E. pungens* Thunb. In the Southern States the fragrant October-flowering species *E. pungens* may be of some value for its fruit and for hybridizing.

ORIENTAL QUINCES

THE oriental or flowering quinces include three species and many varieties, as well as certain hybrids. The best-known species, *Chaenomeles lagenaria* Koidz. (*Cydonia japonica* Pers.), is the so-called Japanese quince, which, however, is a native of central China. It is a spreading shrub with thorny interlacing branches, from 4 to 8 feet high. The dwarf Japanese quince, *Chaenomeles japonica* L., is a sprawling shrub with spiny branches and orange-scarlet blossoms. One hybrid between these two species, named *Chaenomeles superba* Rehd., has blood-red flowers. The flowers of these two species and their hybrids resemble apple blossoms and range from white to salmon and scarlet and even darker. One of the scarlet-flowered varieties most commonly propagated is so covered with flowers in early spring that it is sometimes called "fire bush."

Though ordinarily cultivated for the ornamental value of the bush in flower, the fruit (fig. 7, *A*) is of value for its acidity and pectin content. It has little flavor, but when used in making jelly and preserves with apples, cherries, plums, prunes, and the other cultivated quinces it helps to achieve the balance in the ratio between sugar and acid that is necessary for highest flavor. Tests have been made, in cooperation with the National Preservers Association, to select varieties for this purpose. The variety *grandiflora*, of *Chaenomeles lagenaria*, with fruit 3 to 4 inches in length and weighing one-fourth to one-third of a pound, was the largest and most productive at Glendale, Md., and contained the most malic acid, 5.75 percent.[3] It has apple-pink to rose-pink flowers (fig. 7, *B*).

Because the flowering quinces are largely self-sterile, most people, having only a single bush or only one variety, have never seen the fruit. The varieties *C. lagenaria* var. *baltzii* (cerise-pink flowers), *C. lagenaria* var. *versicolor* (pink flowers), *C. superba* var. *atrosanguinea* (fiery scarlet flowers), *C. japonica* var. *candidissima*, and *C. japonica* var. *nivalis* (white flowers) all bear heavily, and though no tests have been made, some of them may be expected to pollinate the variety *grandiflora* of *C. lagenaria*. Colby,[4] of Illinois, found that *C. lagenaria*

[3] LATHROP, C. P., and WALDE, W. L. THE JAPANESE QUINCE. Fruit Prod. Jour. 7 (4): 14–18, illus.

[4] COLBY, A. S. SOME NOTES ON THE JAPANESE QUINCE. Ill. State Acad. Sci. Trans. (1928) 21: 176–185, illus. 1929.

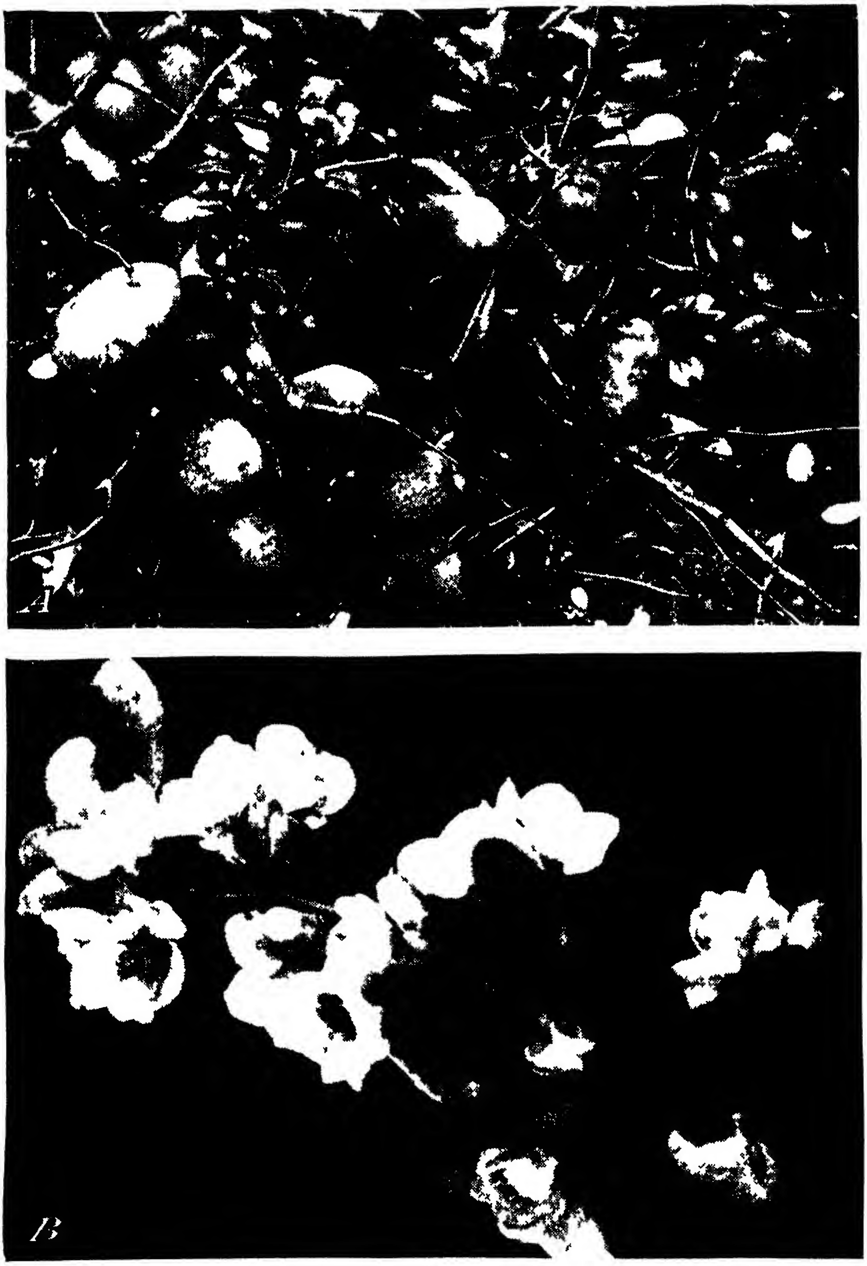

Figure 7.—The flowering quince (*Chaenomeles lagenaria*), a beautiful ornamental but also useful for its fruit (*A*), which is high in malic acid and pectin. *B*, Variety *grandiflora*, propagated originally for its apple-pink flowers but bearing very large fruit of very high acid and pectin content.

var. *grandiflora* was at least partly self-fertile, but no other variety that he tested was at all self-fertile. He has found the fruit of *C. lagenaria* var. *versicolor* fully as large as that of the variety *grandiflora* under his conditions.

The fruits of several varieties are fragrant and are used to perfume rooms. Colby lists the varieties *baltzii* and *atrosanguinea* as having much perfume. The Chinese cover the fruits with a coat of thin oil and keep them in the houses a long time.

Another species from China, *Chaenomeles sinensis* Koehne, is a small tree bearing its flowers singly and having fruit of enormous size, up to 6 inches or more in length. Though its fruit may also be used as a source of acid, it is coarser and has less acid and pectin than the other species. It has a strong flavor, and a small proportion will impart a pleasing suggestion of quince to jelly and preserves made from milder flavored fruits. It is very fragrant and is also used to perfume rooms. The foliage turns a brilliant scarlet in the fall, making it desirable for tall hedges and for ornamental plantings.

The two flowering species, *Chaenomeles lagenaria* and *C. japonica*, are hardy as far north as Massachusetts, New York, and Illinois, and may be raised southward to northern Georgia, or as far south as there is sufficient winter cold to break their rest period. The other species, *C. sinensis*, is hardy north to Philadelphia and may be raised in the South nearly to the Gulf of Mexico.

So far, improvement in the fruit characters of this group has been largely accidental. The high acidity and pectin content of the fruit of some varieties suggests that attempts to obtain still larger amounts would be desirable. Improvement might be made by developing larger sized and more handsomely colored fruit in varieties adapted to different regions, by securing more open growth so that the fruit can be picked more easily, by eliminating thorns on the bushes, and by developing self-fertile varieties. So far no hybrids with the European cultivated quince are known, but attempts should be made to produce them.

The possible importance of this fruit in the preserving industry is indicated by the following quotation from Lathrop and Walde:[5]

> Were a preserver to name the properties most needed in a new fruit by the preserving industry today, he would unwittingly be describing the Japanese quince * * *. * * * its bid for recognition and economic importance is not based upon its becoming a new, distinctive-flavored product. It serves a very different purpose:—to supply a non-flavored fruit, or fruit juice, very high in l-malic acid and pectin to those popular flavored fruits as the apple, cherry, European quince, and plum or prune when requiring additional l-malic acid. * * * These familiar flavors of jellies and preserves when they reach the consumer in many instances do not show off to their best advantage. * * * the marked effect and advantage of making small, definite additions of fruit acid in jellies and preserves was described in the case of some fruits to bring out more of the total fruit flavor actually present.

CHINESE AND OTHER BUSH CHERRIES

THE Chinese bush, Manchu, or Nanking cherry, *Prunus tomentosa* Thunb. (called by the Chinese the mountain cherry),[6] has been grown in the United States some 50 years as an ornamental shrub but now

[5] LATHROP, C. P., and WALDE, W. L. See p. 14 of reference cited in footnote 3.
[6] DARROW, G. M. THE CHINESE BUSH CHERRY . . . Jour. Heredity 15: 169–176, illus. 1924.

is attracting attention for its fruit. It is one of the earliest of all shrubs to flower in the spring, its white to pink blossoms (fig. 8) opening just as the leaves start to unfold and its brilliant red fruit

Figure 8.—Flowers of the Chinese bush cherry. It flowers on the previous season's growth.

(fig. 9) ripening with the last of the strawberries. The fruit has a range in flavor and texture from the sweet to the sour cherry with a peculiarly attractive tang. It is as large as the wild cherries of

Europe, from which the cultivated sweet and sour cherries have originated. The foliage is resistant to the common cherry leaf troubles. The tree is cultivated to some extent in China, and the fruit is also gathered in the wild and sold in the markets. The range of the Nanking cherry in Asia is from southern Manchuria to the Kashmir region of northern India, a region for the most part semiarid and in latitude and climate comparable to the territory from eastern New Mexico northward to North Dakota.

Figure 9.—The Chinese bush cherry in fruit. Its brilliant red fruits range in flavor from the sweet to the sour cherries. They are produced in great abundance provided they escape spring frosts and brown rot. Objectives in breeding this fruit should include late-flowering, brown rot-resistant seedlings.

When they escape spring frosts and severe attacks of brown rot, the bushes are loaded with fruit of the size of small sour cherries. The most needed improvements are the introduction or discovery of late-flowering and brown-rot-resistant seedlings (fig. 10). The brown rot fungus often kills back twigs and branches in humid sections.

Harlow Rockhill, strawberry breeder at Conrad, Iowa, has crossed the Nanking cherry with the western sand cherry, *Prunus besseyi* Bailey, and has grown several generations of hybrid seedlings. He feels that some are very promising for Iowa conditions, as they flower later and are less often injured by cold than the Nanking cherry. Importations are needed from different regions to make selections adapted for the coldest to the warmest, and the driest to the most humid regions of this country. Rockhill has crossed the Nanking cherry with the Napoleon (Royal Anne), Montmorency, and Zumbra cherries, and there is the possibility of obtaining hybrids with many other cherries. The Arnold Arboretum reported having a natural hybrid between *P. tomentosa* and *P. triloba* Lindl. in their plantings.

Slate,[7] of the New York (State) Agricultural Experiment Station, has selected fine fruiting seedlings at Geneva and has started propagating them. By and large, it is a promising fruit for the plant breeder, and it may have commercial possibilities.

Figure 10.—Seedling plants of the Chinese bush cherry, in the middle an early flowering, at the right a later flowering, and at the left a much later flowering sort. These seedlings illustrate the possibility of obtaining much later flowering selections that may escape unseasonable frosts.

Prunus glandulosa Thunb. and *P. japonica* Thunb. are very hardy dwarf shrubs that are ornamental and have deep red to purple-black fruits useful for pies, jellies, and sauce. There are also many other species of bush cherries in Asia that may be worth using in breeding. Besides the bush cherries, *P. triloba*, classed as a flowering almond, is possibly a still more beautiful hardy flowering and fruiting shrub with flowers of pure pink.

IMPROVING THE WILD BLUEBERRY

FREDERICK V. COVILLE, Principal Botanist, Division of Plant Exploration and Introduction, Bureau of Plant Industry

IN 1906 the writer began a series of experiments to learn the fundamental facts in the life history of the blueberry, which might serve as a basis for the possible cultivation of this delicious wild fruit. It took 2 years to find that the blueberry plant requires an acid soil. These experiments showed also that trailing-arbutus, rhododendrons, azaleas, mountain-laurel, pink ladyslipper, and many other plants require acid soils.

Although every gardener today knows that blueberries, as well as hundreds of other kinds of plants associated with blueberries in their wild habitats, thrive only in acid soil, that fact apparently was not known to American horticulturists prior to these experiments with blueberries. The Cyclopedia of American Horticulture, published in four volumes in 1900, and prepared with the collaboration of more than 200 horticulturists and botanists of the United States, contains no mention that an acid soil is required for the successful cultivation of any one of these plants.

Figure 1.—Frederick V. Coville, assistant botanist and principal botanist, United States Department of Agriculture, 1888–1937; first breeder of blueberries and founder of the industry of blueberry culture.

BEST WILD BLUEBERRIES CHOSEN FOR BREEDING PURPOSES

AFTER the soil-acidity requirement of blueberries had been determined, 2 years more were devoted to further studies of the life history of the blueberry, and by the end of 1910, when the first bulletin was published,[1] the blueberry had been grown successfully from seed to fruit; selected plants had been propagated by grafting, budding, division, layering, twig cuttings, and root cuttings; methods of pollination had been devised and applied; and wild plants with superior fruit had been chosen as the basis for breeding experiments.

[1]COVILLE, F. V. EXPERIMENTS IN BLUEBERRY CULTURE. U. S Dept Agr., Bur Plant Indus. Bull. 193, 100 pp, illus. 1910.

DR. COVILLE *died suddenly on January 9, 1937, only a few weeks after he had completed the article that appears herewith. It is fitting that his last paper deals with the greatest of his achievements in agriculture. His work in domesticating and improving the blueberry was based upon years of taxonomic, physiological, and genetic investigation of the wild blueberries of the eastern United States, and the flourishing industry fathered by his efforts rests upon a sure foundation of scientific knowledge.*

Yet the blueberry achievement is but one of many in his chosen science, botany. In 1888, the year after his graduation from Cornell University, he entered the Department of Agriculture, and in 1891 he accompanied the famous Death Valley expedition in the capacity of botanist. As a result there was published in 1893 Botany of the Death Valley Expedition, one of the classics of the study of desert vegetation. Soon Coville was back again in the far West, investigating the useful plants of the American Indians and carrying on, in collaboration with the foresters of the Department, fundamental studies of the grazing and browse plants of the national forests. The present grazing-management policies of the Forest Service are the outcome, in large measure, of these investigations.

No one who had the privilege of being in the field with Dr. Coville could fail to be impressed by his keenness of observation and his constant appreciation of the beauty and the human appeal as well as the scientific interest of plants. The few examples of his work mentioned in the preceding paragraphs give only a partial view of his wide-ranging interest. He published no fewer than 158 scientific papers. Aside from his own special investigations, he played a leading part in such enterprises as organizing the research work of the National Geographic Society, establishing the Desert Botanical Laboratory of the Carnegie Institution of Washington, and founding the National Arboretum. With F. L. Olmsted and H. P. Kelsey, he edited that indispensable aid of the horticulturist, Standardized Plant Names. The writer well remembers Coville's delight, while the book was in preparation, when he or one of his colleagues would hit upon an apt and attractive English name for some plant hitherto known only in Latin or Greek.

Dr. Coville had a host of friends in all walks of life, to whom he was a patient and kindly counselor. Because of his reputation for sturdy good sense, people sought his advice, and he never begrudged for this purpose time that he could ill spare from his many occupations. The deep sense of loss his colleagues feel at his death is intensified by regret that he did not live to make one more trip to Death Valley, the scene of his first important botanical discoveries, as he had planned to do this spring. The popular flora of the Death Valley region he was engaged in writing would have been a most appropriate conclusion of a busy, useful, and happy life.

T. H. KEARNEY.

Brooks Blueberry

The first wild blueberry selected for breeding purposes was Brooks, named after the owner of the pasture at Greenfield, N. H., in which the plant was found. It was a highbush blueberry, *Vaccinium corymbosum* L. The berry was discovered in July 1908, after three summers of cursory observation in the mountains of southern New Hampshire and 3 weeks of diligent search in the summer of 1908. The bush grew at an elevation of 950 feet above the sea. It stood with many other blueberry plants in an old, brushy, mountain pasture, in acid and permanently moist but not swampy soil. It was about 7 feet high, and the largest of the several stems was about 2 inches in diameter. The plant was old, and the tops on some of the stems were partially dead. Other parts of the bush were in full vigor, with robust twigs and foliage. It yielded 3 quarts of berries. The berries were of large size, reaching a diameter of more than half an inch. The flesh was firm and juicy. The color was an unusually light blue, due to a dense bloom over the nearly black surface. In flavor the berry was exceptionally good. It was sweet, but sufficiently acid to be decidedly superior to the mild-flavored fruit of the lowbush blueberry, *V. angustifolium* Ait., yet not sour like the Canada blueberry, *V. canadense* Kalm, and it possessed in a high degree the flavoring ester that is the special characteristic of the best wild blueberries of New England. The delicious flavor of this wild blueberry from New Hampshire appears in all the cross-bred named varieties of blueberries except Jersey and Wareham, and the flavor of those two varieties would be more delicious if Brooks had been included in their ancestry.

This description of the Brooks blueberry has been given in detail because I regard its selection as of fundamental importance to the success of the Department's blueberry-breeding experiments. Every breeder of race horses or of milk cows understands that the choosing of the individuals to be interbred is of the highest importance. Plant breeders usually select carefully the species they intend to interbreed, but often make the mistake of paying too little attention to the choice of superior individual plants within the species.

ATTEMPT TO IMPROVE THE BLUEBERRY THROUGH SELF-POLLINATION A FAILURE

The first attempts to improve the blueberry by breeding were made in 1909 and 1910, when flowers on the original Brooks bush, and on plants propagated from it by grafting, by budding, and by cuttings, were pollinated by hand with Brooks pollen. These flowers did not set fruit, or the fruit withered and dropped long before it was mature, or if a few berries ripened they contained abnormally few seeds, most of these lacking embryos. No plants resulted from the sowing of these seeds. In later years self-pollination was tried repeatedly. In some instances a few plants were obtained from the few seeds resulting from such pollinations, but the plants were weak and they never produced fruit that was either desirable or abundant. This method of breeding, therefore, so successful with corn and with beans, was finally abandoned as a means of improving the blueberry. Before this subject is dismissed, however, it may be well to cite an experiment

in 1914 which shows how definite is the tendency to failure in self-pollination as compared with cross-pollination in the blueberry. On February 23 to 28 of that year 20 flowers on a hybrid blueberry plant known as 393C were pollinated with pollen from another hybrid blueberry, 394Y. Nineteen of these twenty cross-pollinated flowers set fruit and 19 berries ripened. On February 27 and 28, six flowers on 393C were pollinated with the plant's own pollen. From these six self-pollinated flowers no berries ripened. Five of the six flowers set fruit at first, but these all shriveled and dropped while they were still young and green. The failure of 393C to produce seeds when pollinated with its own pollen was not due to sterility of the pollen, for the pollen of this plant, when used in another experiment, on 394Y, yielded an abundance of berries and seeds from which many vigorous and productive plants were grown

NUMBER OF CHROMOSOMES IMPORTANT

ANOTHER series of failures in the early blueberry pollinations was due to a cause quite different from self-sterility. Certain species of blueberry usually yielded no fruit when cross-pollinated, among them the lowbush blueberry and the Canada blueberry, species of similar size and habit, which occur together in enormous areas on both sides of the Canadian border; the highbush blueberry and the bigbush blueberry, *Vaccinium atrococcum* (A. Gray) Heller, which resemble each other so closely that Asa Gray considered one a variety of the other; and the highbush blueberry and the dryland blueberry, *V. vacillans* Kalm. When the two species of any of these pairs were cross-pollinated they usually produced no fruit. If, however, any berries resulted from the cross-pollinations, their few seeds produced weak and unproductive plants. In later years, cytological studies by Longley [2] showed that in each of these pairs the first-named species has 24 chromosomes; the other 12 The 12-chromosome species, it was found later, cross freely with each other. They even cross with the deerberry, which belongs to a related genus, *Polycodium*, but which has 12 chromosomes.

Among the 24-chromosome species of blueberry, crosses could be made easily, notwithstanding great differences in the physical appearance of the two species that were crossed. Not only were the highbush and the lowbush blueberry hybridized by artificial pollination, but natural hybrids between them are of frequent occurrence in New England pastures. The highbush blueberry grows to a height of 7 feet, with many stout stems in a single clump, and its leaves are commonly 2 to 2½ inches long by 1 to 1½ inches wide, the margins usually without teeth. The lowbush blueberry is 6 inches to a foot in height. It spreads by slender rootstocks into broad patches, and its leaves are small, narrow, and finely serrate. The highbush blueberry is easily crossed also with the myrtle blueberry of Florida, *Vaccinium myrsinites* Lam., a 2-foot species with evergreen, minutely-toothed leaves, which are seldom more than three-fourths of an inch in length. The highbush blueberry can be crossed easily also with the hairy blueberry, *V. hirsutum* Buckl., a southern-Appalachian species 2 to

3 feet high, with leaves densely pubescent on both surfaces, and with hairy, black berries. In a word, ease of crossing, among blueberry species of the eastern United States, is dependent on equality of chromosome number. Blueberry species of the most diverse appearance and characteristics, but with the same number of chromosomes, hybridize readily.

Russell Blueberry

The second wild blueberry selected for breeding purposes was Russell. It was brought to my attention in 1909 by Frank Russell as the best lowbush blueberry on his 600-acre mountain farm at Greenfield, N. H. The original plant had become so shaded by the low branches of a young oak tree that it no longer produced fruit, but in the greenhouses at Washington its berries reached a diameter of over nine-sixteenths of an inch. The berries were light blue in color, and they ripened earlier than those of Brooks. This tendency toward earliness appears in all the progeny of the Russell blueberry and is of great commercial importance because the earliest of the improved blueberries often bring the highest prices.

FIRST BLUEBERRY HYBRIDS

The first cross-pollinations between Russell and Brooks were made in the spring of 1911. Some of the resulting first-generation hybrids were cross-pollinated with each other in 1913. The resulting progeny, about 3,000 hybrids of the first and second generations, was grown to maturity in the field, with remarkable results.

The outstanding characteristic of these hybrids was the variation in the color of their fruit The berries of both Brooks and Russell are of light blue color. The body of the berry in both varieties is a dark purple, which appears as a black when the bloom is rubbed off. In the first-generation hybrids of Brooks and Russell the bloom was much thinner than in either parent, and in consequence the berries of the hybrids were dark blue in color, in strong contrast with the light blue berries of both parents. One of these first-generation hybrids is shown in figure 2. When two of these dark-berried first-generation hybrids were interbred the resulting second-generation hybrids showed a still more remarkable diversity of color. On about 65 percent of the plants the berries were dark blue, just as in the first-generation hybrids. On about 18 percent they were black, some of them a dull black, some without a trace of bloom, so that the berries had the shining appearance of a black shoe button. On about 15 percent of the plants the berries were light blue, like the berries of both grandparents. On about 1.5 percent the berries were albinos. They lacked the purple coloring matter that, located in the skin of the blueberry, gives the fruit the black color that appears when the bloom is rubbed away. Further comments on these albino blueberries are given later in this paper under the varieties Redskin and Catawba. On about 0.5 percent of the plants the heavy bloom of the berries on the two grandparents was replaced by an apparently still denser and lighter colored bloom which gave the berry a metallic luster like that of new aluminum ware.

A shining black color in these blueberry hybrids was never found associated with a delicious taste, perhaps because there was not a

sufficient number of such plants to afford an adequate range in flavor. The same was true of the "aluminum" berries. In the dark-colored berries excellent flavor and good size were often combined. These

Figure 2.—One of the first blueberry hybrids. This is a first-generation cross between a wild highbush blueberry, Brooks, and a wild lowbush blueberry, Russell, from Greenfield, N. H. Another hybrid of the same parentage, 394Y, was one of the ancestors of the varieties Rancocas, June, and Weymouth. (Natural size.)

dark-berried bushes of 2- to 3-foot stature are of frequent occurrence in New England pastures as natural hybrids between *Vaccinium corymbosum* and *V. angustifolium.* Such a hybrid is the plant described in Gray's Manual of Botany and Rehder's Manual of Cul-

tivated Trees and Shrubs as *V. corymbosum amoenum.*[3] About Greenfield, N. H., the plants of such hybrids are popularly known as the half-high blueberry. For many years I regarded this plant as a distinct species, until it appeared by hundreds among the artificial hybrids.

Sooy Blueberry

An important step forward in blueberry breeding came about by enlisting the interest of wild-blueberry pickers in New Jersey through cooperation with Elizabeth C. White, of New Lisbon, N. J. On July 20, 1911, I stopped at the house of Ezekiel Sooy, an experienced picker of wild blueberries, living at Browns Mills. It had been stipulated that a wild blueberry, to be valuable, must be half an inch in diameter. Mr. Sooy said that he hadn't any half-inch blueberries for me, that all the good bushes had berries much larger than that. He proceeded to take me to one of them, near the road, a mile east of his house. The berry proved to be a beauty, five-eighths of an inch in diameter. I started to arrange that a portion of the bush be taken up later when the plant was dormant, but Mr. Sooy took hold of a rooted sucker about an inch in diameter and ripped it from the ground with a forceful yank. I had been in the habit of treating blueberry plants with consideration and when I protested that the plant had been taken up neither at the proper season nor in the proper manner, Mr. Sooy said, "That root will grow. You can't kill a blueberry bush." So the top was cut off and the root was wrapped in a wet newspaper and taken to Washington, where under the name Sooy it became one of the progenitors of some of our best blueberry hybrids.

Brooks and Sooy were cross-pollinated in 1912. Nearly 3,000 seedlings of this parentage were grown to maturity in the field. Among them were two plants that when propagated from cuttings became the improved blueberry varieties Pioneer and Katharine

THOUSANDS OF PEDIGREED SEEDLING BLUEBERRIES TESTED TO OBTAIN 15 NAMED VARIETIES

Up to the year 1936 about 68,000 pedigreed blueberry seedlings have been fruited and carefully examined to determine which were sufficiently valuable to be propagated and distributed as named varieties. The ancestry of each seedling is a matter of record. In the testing plantations it was sometimes evident from the characteristics of an individual plant that it did not belong to the group indicated by the record. Somewhere during its life, when it was placed in the ground as a seed, or when it was potted in the greenhouse, or when it was packed for shipment, or when it was placed in the field nursery, or when it was set in its final place in the testing field, it was exchanged with another plant that had a different history. It happens, however, that none of these evidently misplaced plants has proved to be of such high quality that it deserved to be named. We are able to say, therefore, that the ancestry of our named varieties of improved blueberries is above suspicion.

TESTING BLUEBERRIES

The selection of the few best plants in a field containing thousands of individual pedigreed blueberry seedlings is a tedious business. It requires sustained attention and keen and repeated observations. As one walks down the rows, the desirable color of an exceptionally light-blue berry can be observed almost at a glance. If, however, the branches of the plant are unusually flexible, the wind swaying a heavy cluster of berries against a neighboring branch may wipe away the bloom and disfigure the berries by leaving them black on one side. Stiffness of branch is needed to insure uniformity in the color of the berries.

To be sure of the size of a blueberry, one's judgment needs to be checked continually with a gage. The gage illustrated in figure 3 was in use for several years until its largest hole, 25 millimeters (an inch is 25.4 mm), was found to be too small to measure the largest hybrid blueberry. This is the one described later in this paper as GM37 and illustrated in figure 4. The original Brooks blueberry slightly exceeded 14 mm, the Russell blueberry 15 mm, and the Sooy blueberry 16 mm. Our largest hybrid that has a delicious flavor has thus far attained only 24 mm in diameter.

The ease of picking and the size of the scar on the blueberry where it separates from its stem are important. A small and dry scar is the most desirable, and such a scar is usually associated with ease of picking. Further notes on difficulty of picking are given later under the variety Katharine, and on ease of picking under the variety Rancocas. An undesirable feature was observed in some of the seedlings when the joint at the base of the stem of the individual berry separated more easily than the joint at the upper end of the stem, and the stem therefore remained attached to the berry when it was picked. Such a berry is undesirable commercially.

In many of the seedlings the skin at the base of the blueberry tends to remain attached to the stem and, in picking, a piece of skin is torn from the berry. A seedling bearing such berries is always rejected, however good its flavor and other qualities.

The keeping quality and the firmness of flesh must be considered in selecting a blueberry, because under commercial conditions berries without these qualities may not reach the consumer in good condition. A blueberry is often rejected if it has a very large calyx. Such a calyx may afford a place for an insect to hide.

Occasionally the ripe fruit of a blueberry tends to crack after a rain. The crack may come between the calyx lobes, where the skin is sometimes tightly stretched as the berry enlarges and ripens, or it may form about the middle of the berry. Several blueberries of large size and delicious flavor have been rejected because of their tendency to crack.

Testing for Flavor

Probably the most elusive and difficult thing to judge in a new blueberry is its flavor. After several hours of tasting, all blueberries taste alike, and they all taste sour. On a day in which many blueberries are to be tried for flavor, I never swallow the berries I am tasting, and I taste only those that appear promising from their size

and other visible qualities. Even with such precautions to conserve one's ability to distinguish flavors, it sometimes is necessary to stop work in the field until one's organs of taste have recovered their faculty of discrimination. If a blueberry is to be eaten in a pie, its flavor is of secondary importance, for if it has not sufficient acidity a teaspoonful of vinegar, or its equivalent in lemon juice, will supply the deficiency; but if the blueberry is to be eaten as a fresh fruit, either out of hand or with cream and sugar, its flavor, its seedlessness, and its succulence are its chief contributions to enjoyment.

A blueberry is sweet, slightly sweet, or quite without sweetness. It may be sour, slightly acid, or flat. It may have none of the special flavor of the blueberry, or a little of it, or this flavor may be present in a high degree. Its flesh may be lacking in juiciness, or it may be juicy and sprightly. When taken directly from the bush, the blueberry varies in taste with its degree of ripeness. When blueberries first turn blue they usually are still sour. When they have been blue about a week they commonly are ready for picking, but the berries of some of the varieties with relatively sour fruit may need to remain on the bush for 2 or even 3 weeks after they turn blue, before they become really palatable.

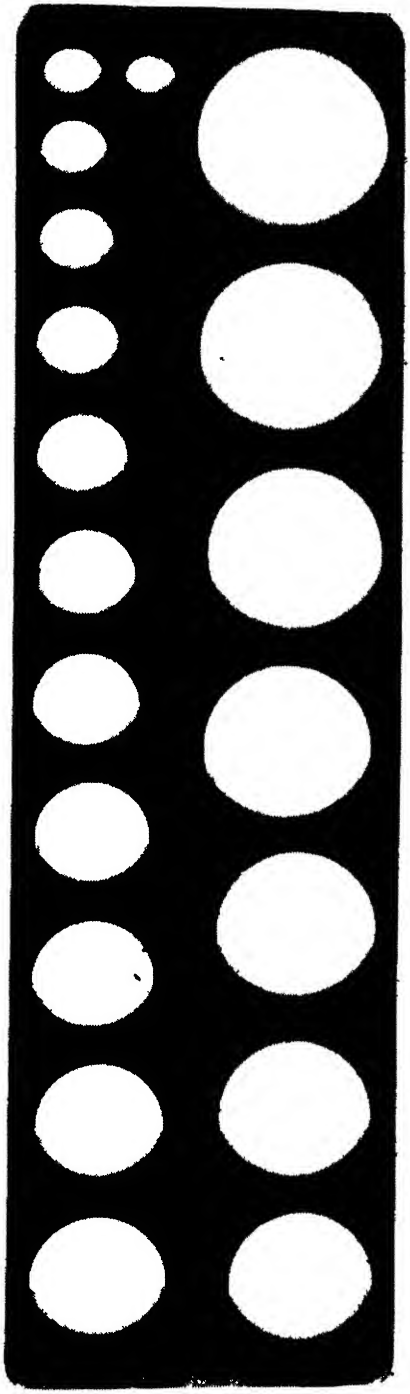

***Figure 3.*—A blueberry gage, the holes from 7 mm (a little more than a quarter of an inch) to 25 mm (a little less than an inch) in diameter. The largest blueberry thus far grown is a little larger than the largest hole in this gage.**

Individual preferences vary regarding the taste of blueberries. Some persons prefer a blueberry so sour that it cannot be eaten without liberal quantities of sugar. My own preference is for a blueberry that is juicy, sweet, with a slight acidity, and with the characteristic blueberry flavor highly developed. If such blueberries are sound, and for about 2 days after picking, can be kept in a shady, breezy place, without refrigeration, preferably until they have begun to shrivel very slightly, they are then in their ideal condition for flavor, and are ready to go into the refrigerator for chilling before they are served.

In the field it has seemed difficult to find a satisfactory flavor in a blueberry on a very hot day. Whether the fault is with the blueberry or with the taster I cannot say. In tasting blueberries in the field, one may easily make an error of judgment if the berry he tastes is blue but not really ripe. If the berry is in an underripe condition it will have a purplish color around the scar where it separated from its stem. If the berry is of normal color and is fully ripe the area around the scar will be of the same color as the rest of the berry.

To avoid the introduction of new blueberry varieties that are chiefly valuable to the grower only, because of their productiveness and their shipping quality, it has been the aim of the Department, in its blueberry breeding, to consider the consumer also, and especially to develop for his benefit varieties of high flavor. As evidence of the faithfulness of this endeavor it may be recorded that more than 300 seedling blueberry plants that bore berries over three-quarters of an inch (19.1 mm) in diameter have been destroyed because they did not come up to the standards we have set for flavor.

PROPAGATING NEW VARIETIES

When a seedling is of such high quality that it is considered worthy of propagation and distribution as a new and named variety, single buds taken from it are inserted, in midsummer, near the base of new shoots that have grown from older blueberry plants cut to the ground in the preceding winter. In the following spring each shoot is cut off just above the inserted bud, and no other bud is allowed to grow. By the end of the season the plant has a top of nearly the same size as the top that was cut off two seasons before, and this new top furnishes many cuttings of the new variety. By this procedure a new variety of blueberry can be propagated many times more rapidly than if the cuttings were taken directly from the single original plant.

THE IMPROVED VARIETIES OF BLUEBERRY

Pioneer

Pioneer was so designated because it was the first named variety developed as a result of blueberry breeding. It was a first-generation cross between the wild highbush blueberries Brooks and Sooy, made in 1912. Like all the improved varieties not otherwise described, its leaves have no teeth on their margins. Its berries are of light blue color, sweet, of excellent flavor, and when fully ripe are without acidity. The largest berry on the original bush was 18.5 mm in diameter. Young Pioneer plants in commercial fields have borne berries up to 19.7 mm. Pioneer is a midseason variety.

Greenfield

Greenfield was a second-generation hybrid between Brooks, a highbush blueberry, and Russell, a lowbush blueberry, both of them wild plants from Greenfield, N. H. The leaves of Greenfield were finely toothed. The seed from which the plant was grown came from a cross-pollination made in the spring of 1913. The variety never became established in commercial blueberry culture, and is recorded here only for the purpose of accounting for the name.

Cabot

The Cabot blueberry is a first-generation hybrid between two wild highbush blueberries, Brooks, already described, and Chatsworth, which was found near the settlement named Chatsworth, in the pine barrens of New Jersey. The cross-pollination was made in 1913. The bush was named for my son, Cabot Coville, now secretary of the American embassy at Tokyo, who chose this bush for the flavor of its berries, which have a slight acidity, in preference to the sweet, nonacid berries of Pioneer. Cabot is an early variety, for many years the earliest of the named varieties, and in consequence it has been planted very extensively by blueberry growers. It has been found desirable to pick its berries about twice a week, and a bush sometimes yields as many as seven pickings. The berries on the original bush reached a diameter of 18.5 mm. For some obscure reason the fruit buds of the Cabot blueberry, in late winter, are a morsel fascinating to deer. At the blueberry plantation known as the Ore Ponds, a few miles west of Toms River, N. J., the deer almost denuded the Cabot bushes of their fruit buds in the early spring of 1928. In consequence of this excessive pruning by deer, the remaining buds produced berries up to 20.5 mm in diameter, an unusually large size for this variety.

Katharine

The Katharine blueberry is of the same parentage as Pioneer. It was a first-generation cross between the wild highbush blueberries Brooks and Sooy, from a pollination made in 1913. The berries are light blue and of especially delicious flavor. On the original bush they reached a diameter of a little over 19 mm. Occasionally in commercial plantations they reach 20 mm. The Katharine is hard to pick. The berry clings tenaciously to its stem, and when it is pulled away a hole is often torn in the base of the berry. The injury detracts from both the appearance and the keeping quality of the berries, yet in spite of this defect the Katharine is a variety that has been very satisfactory to the consumer. The Katharine is named after my daughter, Katharine, now Mrs. Chester C. Woodburn, of Des Moines, Iowa, who in one of her high-school years did all my blueberry pollinations. The variety ripens a little later than Pioneer.

Rancocas

One of the parents of Rancocas was an unnamed blueberry hybrid known as 394Y, a first-generation cross between Brooks and Russell. The other parent was a wild blueberry from the pine barrens of New Jersey named Rubel. This is, in form, the German spelling of the

name of the old Russian coin, the rouble. The name of the blueberry variety Rubel, however, is of neither German nor Russian derivation. The man who discovered this bush was Rube Leek. Rube did not seem an expressive name for a berry that was blue and beautiful, and Leek was suggestive of a flavor that the berry did not possess. Rubel was a compromise, made up of Mr. Leek's first name and the initial of his last. The seed from which the Rancocas bush grew was the result of a pollination in the spring of 1915. Rancocas is a second-early variety, ripening its berries later than Cabot and earlier than Pioneer. The original bush bore berries up to 18 mm in diameter. Berries in commercial plantations sometimes exceed 19 mm. Rancocas tends to the production of heavy crops on young and healthy bushes, so heavy indeed that unusual care must be taken to prune the bushes severely in order to insure a good crop in the following year. The leaves of Rancocas have finely toothed margins. The berries have a small, dry scar and are very easily picked. The name of this variety came from Rancocas Creek in New Jersey. Near this creek was the blueberry plantation in which the variety gave its first satisfactory performance.

Jersey

The variety Jersey was so named because both its parents were wild plants from New Jersey. These parents were Rubel, already described under Rancocas, and Grover, discovered by Russell Grover. The two were cross-pollinated in 1916. Jersey is a variety maturing late in the season, so late in fact that its berries often bring a high price, in northern plantations, because of its lateness. This and other late varieties extend the blueberry-picking season over a period of about 8 weeks, the early varieties beginning to ripen in New Jersey in the latter part of June and the late varieties continuing until the middle of August and sometimes later. The berries of Jersey are large, up to 22.4 mm in diameter, and, until dead ripe, too acid for the taste of most persons. Jersey is of remarkably robust growth, the leaves on vigorous shoots sometimes attaining a length of 4 inches and a width of 2¼ inches.

Concord

The Concord blueberry was so named because of its large clusters of berries, which, all ripe at the same time, resemble clusters of Concord grapes. It is a first-generation hybrid between the wild highbush blueberries Brooks and Rubel and came from a cross-pollination in 1917. The original bush bore berries up to 18 mm in diameter. In field culture its berries sometimes reach a diameter of 20 mm, occasionally 21 mm. Concord berries are delicious when they are allowed to remain on the bush until they are fully ripe and have lost the excessive acidity they possess when they first turn blue. Concord is a midseason variety, ripening at about the same time as Pioneer.

June

June, named for its early ripening in New Jersey, is of the same parentage as Rancocas, but from cross-pollinations made in 1919. On the original bush the berries reached a diameter of 20 mm. In commercial plantations they have sometimes exceeded 21 mm. The berry

is of medium blue color, sweet and delicious when fully ripe, with a slight subacidity. It usually ripens earlier than Cabot. Although June is of one-fourth lowbush ancestry, its leaf margins do not have the teeth that characterize its lowbush grandparent.

Scammell

The Scammell blueberry is named for H. B. Scammell, of Toms River, N. J., who first showed how good are the qualities of this berry under field conditions. One of the parents of the Scammell was a cross between the wild blueberries Brooks and Chatsworth. This Brooks-Chatsworth parent, which was never planted in the field, was recorded in the greenhouse in Washington as having "berries of delicious taste, sweet, slightly acid and of pronounced flavor." This plant was pollinated with Rubel pollen in 1915, and the Scammell blueberry was one of the resulting seedlings. In the field the original bush of Scammell bore berries up to a diameter of 20.5 mm. On budded plants in the greenhouse in Washington they reached more than 22 mm. The berries have a medium blue color, firm texture, and a small scar, and the calyx is almost wanting. The leaves are smaller than on most varieties of highbush ancestry, commonly 1½ to 2 inches in length and five-eighths to three-quarters of an inch in width. The berries are sweet, subacid, and have a high degree of flavor. They ripen in late midseason. Among New Jersey growers there has been little planting of this variety, apparently from doubt regarding its vegetative vigor. In North Carolina, however, at the Double Trouble Company's blueberry plantation near Magnolia, it is regarded as one of their best varieties.

Stanley

The Stanley resulted from a cross between the Katharine blueberry and the wild Rubel bush, made in 1921. By many persons Stanley is considered the most delicious of all blueberries. The original bush bore berries a little less than 18 mm in diameter. From the first its berries were recognized as of especially delicious flavor. It is named for my son, Stanley, on whose blueberry plantation at New Lisbon, N. J., this variety was first shown to be capable of producing good yields of berries of large size. Its berries often exceed 19 mm in diameter and sometimes 20 mm. In one instance a Stanley berry reached a diameter of 21 mm and in another instance 22 mm. The Stanley blueberry is a late midseason variety.

Redskin

The Redskin blueberry is an albino, a second-generation hybrid between the wild highbush blueberry Brooks and the wild lowbush blueberry Russell. The original Redskin plant came from a pollination made in 1913. Albino blueberries become red on the side exposed to the sun. In the Redskin blueberry the red is almost that of old mahogany, with only a trace of bloom. The berry sometimes exceeds 16 mm in diameter, and the flavor is good. The berry ripens early in the season. This variety and the next, Catawba, were given names in 1932 because as red-cheeked albinos they are horticultural curiosities. The fair size and good flavor of their berries make them desirable additions to a collection of blueberry varieties for a home garden. It

is doubtful whether any albino blueberry will ever acquire importance as a market fruit. The white color of the shaded half of the Redskin berry gives the fruit a mottled appearance after picking, and on any slight bruise the injured portion of the flesh turns to a dried-apple color, both of these features making the fruit uninviting to a purchaser. The leaves of Redskin are finely toothed. This variety should be pruned at the end of the growing season by the removal of all the stems that fruited in the preceding summer, only the season's sprouts being left. When so pruned, Redskin hardly reaches a height of 2 feet. This low stature, which allows the plants to be kept covered with snow very easily during the bitter cold of a northern midwinter, suggests Redskin as a desirable variety in places so far north that other and taller varieties project through the snow and lose their fruit buds by winter-killing.

Catawba

The Catawba blueberry is an albino which was bred from the same grandparents and the same parents as Redskin, and in the same year. The berries of Catawba are not so large as those of Redskin, nor is their flavor quite so good. They have more bloom, and the red of the berry is therefore paler than in redskin, more like the color of the Catawba grape, a resemblance that suggested the varietal name. The leaves of the Catawba are finely toothed, and the plants reach a height of about 4 feet.

Wareham

In the autumn of 1916 some 300 pedigreed but untested blueberry seedlings were sent to the cranberry substation of the Massachusetts Agricultural Experiment Station, East Wareham, Mass., to be brought into fruit by H. J. Franklin, in charge of the cranberry substation. Among these seedlings was one that, after several years of observation, Professor Franklin thought was of sufficient merit to be named and distributed. In accordance with his wish it was named Wareham. The parents of the Wareham blueberry were the wild New Jersey highbush blueberry Rubel and another wild New Jersey highbush blueberry named Harding, after its discoverer, Ralph Harding. The cross-pollination was made in 1915. The original bush of the Wareham blueberry, in the late summer of 1931, had a breadth of 9 by 9 feet and a height of 6 feet. It was vigorous and had produced 8 quarts of berries that season. It differed from most other tall varieties of blueberries improved by breeding in having serrate leaves, like its Harding parent. When I saw the bush again, on July 28, 1933, its berries had not yet been picked. Several were over 19 mm in diameter, some of them nearly 20 mm. Wareham is a late-season variety, its berries maturing at about the same time as Jersey. Until they are dead ripe they are a little too acid for the taste of most persons. When fully ripe they are sweet-subacid and of good flavor.

Weymouth

The Weymouth is named for the cranberry and blueberry plantation of Weymouth, at which most of the Department's testing of new pedigreed blueberry seedlings has been conducted since 1929, between Hammonton and Mays Landing, N. J. It is near Weymouth Furnace, long ago abandoned, at which cannon and cannonballs were

made from bog iron ore during the War of 1812. The Weymouth blueberry is a cross between the two early varieties June and Cabot. The pollination was made in 1928. Although the earliness of Weymouth is not yet satisfactorily proved from commercial field experience, the original bush bore berries that reached nearly 22 mm in diameter and ripened much earlier than Cabot. The berries have only a moderate degree of acidity in the early stage of their ripening, and they are sweet, subacid, and delicious when they are first picked. They lose much of their taste if they are allowed to become overripe.

GM37

There is one seedling blueberry that, although barred from commercial culture because its berries are deficient in flavor, has other such desirable qualities, including the extraordinary size of its fruit, that acquaintance with this unnamed bush ought to be shared with the public. It is known in our records as GM37. It is a cross between Jersey and Pioneer, and therefore has four wild highbush ancestors, Grover and Rubel, the parents of Jersey, and Brooks and Sooy, the parents of Pioneer. The pollination from which GM37 came was made in 1925. The original bush produced berries in 1928 over 20 mm in diameter, in 1929 over 21 mm, and in 1930 nearly 23 mm. In 1933 a budded bush of GM37, hand-pollinated and screened, in a New Jersey blueberry plantation, produced berries up to 25.9 mm, a little over an inch, in diameter. (An inch is 25.4 mm.) A cluster of berries from this bush is illustrated, natural size, in figure 4. The reader should bear in mind that this is the largest blueberry ever produced, but it lacks the flavor required to warrant making it a named variety. For breeding purposes, however, GM37 has great value, as will be evident from what is said under the next variety, Dixi.

Dixi [4]

The unnamed blueberry GM37 lacked only flavor to make it a valuable variety. In 1930 it was cross-pollinated with the Stanley blueberry, the most delicious of all varieties. Among the progeny was a bush that attracted attention first in 1935 and again in 1936. Its berries are sweet-subacid and delicious. On July 9, 1935, the largest berry was over 21 mm in diameter, and on July 24 of that year over 23 mm. On July 24, 1936, the largest berry reached 24 mm. If the season of 1936 had been a favorable one for the development of large individual blueberries, I am confident that the berries on this plant would have reached a diameter of more than an inch. There is now only a single bush of this variety. It will be several years before it can be propagated for a thorough field test of its qualities. Nevertheless, there are circumstances that seem to make it desirable to give a name to this variety at this time. Toward the end of the present fiscal year I terminate my connection with the Department of Agriculture after 49 years of botanical research. It was the custom of Linnaeus and other scientific men of his time, when a

[4] Blueberry growers should be careful not to misspell the name of the Dixi blueberry, for the wrong spelling "Dixie" may give the erroneous impression that this variety is especially adapted to cultivation in the South. The ancestors of the Dixi blueberry were northern plants, and although the variety may be of value as far south as North Carolina, there is every reason to expect that it will not thrive in the Gulf States.

public address was given in Latin, to end the address with a Latin word that meant "I have spoken," "I have said what I have to say," or "I am through." Therefore, with orthographic apologies to the southern half of the United States, I name this blueberry and end this paper with that Latin word—*Dixi*

Figure 4.—A cluster of the largest blueberries thus far grown. (Natural size.) The largest berry on this bush was 25.9 mm (a little more than an inch) in diameter. This bush, known in our records as GM37, was not made a named variety because its berries were not up to our standard of flavor. It has been cross-bred, however, with the most delicious variety of blueberry, Stanley. Among the off-spring is the large and delicious blueberry described in this paper as Dixi, which already, as a young plant, has produced berries nearly as large as those shown in this illustration.

PROGRESS IN APPLE IMPROVEMENT

J. R. MAGNESS, Principal Pomologist,
Division of Fruit and Vegetable Crops
and Diseases, Bureau of Plant Industry[1]

THE apple we have today is far removed from the "gift of the gods" which prehistoric man found in roaming the woods of western Asia and temperate Europe. We can judge that apple only by the wild apples that grow today in the area between the Caspian Sea and Europe, which is believed to be the original habitat of the apple. These apples are generally only 1 to 2 inches in diameter, are acid and astringent, and are far inferior to the choice modern horticultural varieties.

The improvement of the apple through the selection of the best types of the wild seedlings goes far back to the very beginning of history. Methods of budding and grafting fruits were known more than 2,000 years ago. According to Unger, Cato (third century, B. C.) knew seven different apple varieties. Pliny (first century, A. D.) knew 36 different kinds. By the time the first settlers from Europe were coming to the shores of North America, hundreds of apple varieties had been named in European countries.

The superior varieties grown in Europe in the seventeenth century had, so far as is known, all developed as chance seedlings, but gardeners had selected the best of the seedling trees and propagated them vegetatively.

The early American settlers, particularly those from the temperate portions of Europe, who came to the eastern coast of North America, brought with them seeds and in some cases grafted trees of European varieties. Within a few years after the first settlements were made in the temperate portions of North America, bearing apple trees were reported.

From this start, apple trees were rapidly disseminated. The apple was apparently carried by Indians, traders, and missionaries into the wilderness far beyond the white settlements. In the early writings frequent mention is made of Indian villages with apple and peach

---

[1] This article is made possible only through the cooperation of many workers on apple breeding in both the United States and Europe. Reports on which portions of this discussion are based have been received from the following State agricultural experiment station workers: Leif Verner, Idaho; M. J. Dorsey, Illinois; J. L. Lantz, Iowa; R. M. Bailey, Maine; A. L. Schrader, Maryland; J. K. Shaw, Massachusetts; W. H. Alderman, Minnesota; Paul H. Shepard, Missouri; State Fruit Experiment Station; A. E. Murneek, Missouri; Richard Wellington and G. H. Howe, New York (State) Station; F. S. Howlett and C. W. Ellenwood, Ohio; N. E. Hansen, South Dakota; Fred W. HofMann, Virginia; also from W. P. Baird, U. S. Northern Great Plains Field Station, Mandan, N. Dak ; C. P. Close, U. S. Department of Agriculture, Washington, D. C.; T. F Ritchie, acting Dominion horticulturist, Central Experimental Farm, Ottawa, Canada; Sir Daniel Hall, director, John Innes Horticultural Institution, Merton, England; Carl G. Dahl, Lantbruks, Mojeri-och Trädgårdsinstitut, Alnarp, Sweden; Ing. Fr. Landovský, State Institute for Horticultural Research, Průhonice, Czechoslovakia; Prof. Dr. Rudorf, Kaiser Wilhelm Institut für Zuchtungsforschung, Müncheberg, Germany; and H. Wenholz, Department of Agriculture, Sydney, New South Wales, Australia.

orchards adjacent to them; apparently the Indians were an important factor in the early dissemination of these fruits. All the Indian orchards consisted, of course, of seedling trees. Since the apple does not come true from seed, wide variations in size, color, and quality of fruit and season of ripening undoubtedly occurred in these early orchards. As the country became more settled, farmers and gardeners were interested in growing the best of these seedlings rather than in planting a miscellaneous assortment that could be secured from seed.

It is uncertain just when the first grafting of apple varieties was practiced in the United States. Taylor (*15, pp. 308–309*) [2] says:

> Certain it is that in 1647 the apple is recorded as grafted upon wild stocks in Virginia, while in 1686 William Fitzhugh, in describing his own plantation, mentions "a large orchard of about 2,500 apple trees, most grafted, well fenced with a locust fence." * * * Frequent importations of seeds, scions, and grafted trees, together with propagation from those already noticed, both by seeds and grafts, brought the orchards of New England up to such point that Dudley, in 1726, stated in a paper in the Philosophical Transactions, "our Apples are without doubt as good as those of England, and much fairer to look to, and so are the Pears * * * Our People of late years, have run so much upon Orchards, that in a village near Boston, consisting of about forty Families, they made near ten Thousand Barrels [of cider]."

[2] Italic numbers in parentheses refer to Selected References to Literature, p. 601.

APPLE *breeding is a task that requires not only great patience but ability to look well into the future. In most sections of the United States at least 10 to 15 years are required to grow an apple from seed to bearing age and to obtain an accurate evaluation of it. To propagate and test a promising kind will require an additional 10 to 12 years. Therefore not less than 25 years are usually required from the time a cross is made until the progeny of that cross can be fully evaluated. Additional years must then elapse before commercial orchards come into fruiting. Thus it usually takes from 30 to 40 years between the planting of the original seed and the production of commercial crops of even a very superior apple. Apples originating from the earliest breeding investigations in the United States, begun as far back as 1880, are just now coming into prominence; those from the breeding work of 20 or 25 years ago are not yet fully tested. It is easy to see, then, why few of our popular commercial varieties have as yet resulted from modern breeding work. However, there is every prospect that varieties superior to those now in use will result from the many thousands of hybrid seedlings now under test at various research centers.*

As settlements spread westward to the Mississippi Valley and on to the Pacific, apple planting kept pace. An eccentric missionary, John Chapman, known as "Johnny Appleseed", roamed the frontier settlements of Ohio and Indiana in the early nineteenth century, planting apple seed and starting orchards wherever he went and encouraging others to do the same. He lived to see bearing trees throughout the area. Thus the apple became more or less naturalized throughout the temperate part of North America.

The apple varieties grown here today are quite largely those that have been developed from the seedling trees that happened to be superior. Only a few of our important commercial varieties have been imported from Europe. During the past century the primary emphasis in the United States has been on varieties with superior dessert and cooking quality, along with good size, a range of ripening from midsummer to late fall, and a storage quality that will carry the fruit through the winter months. Perhaps the greater emphasis in Europe on the use of apples for cider making is partially responsible for the smaller number of really high-quality dessert apples selected there. Table 1, in the appendix, indicates the source of leading American varieties of apples so far as it is known.

Few of the apples that have reached commercial promise to date have been produced as a result of systematic hybridization. The reason for this is readily apparent when certain of the factors involved in apple breeding are considered. Practically no systematic work was started in the United States prior to 1880, and little was carried on prior to 1895. In most sections of the United States at least 10 to 15 years are required to grow an apple tree from seed to bearing age and to give an accurate evaluation of it. To propagate and test a promising kind will require an additional 10 to 12 years. Therefore not less than 25 years is usually required from the time a cross is made until the progeny of that cross can be accurately evaluated. Additional years must then elapse before commercial orchards come into fruiting. Thus from 30 to 40 years will usually elapse between the planting of the original seed and the production of commercial crops of even a very superior apple. Apples originating from the earlier breeding investigations are just now coming into commercial prominence. Since much of the breeding work has been conducted during the last 20 or 25 years, sufficient time has not yet elapsed to give a full evaluation of the offspring of the crosses made.

THE RAW MATERIALS OF THE APPLE BREEDER

The apple belongs to the great family of plants termed by botanists the Rosaceae, or rose family. This family is very large and includes many tree fruits of the Temperate Zone, such as plums and prunes, peaches, cherries, apricots, and pears, as well as strawberries, blackberries, and many other forms of cultivated and wild plants. Apples and pears belong to the pome fruit subfamily Pomoideae, which includes, in addition to these fruits, the hawthorns, cotoneasters, quinces, medlars, mountain-ash, and a number of additional related forms. All of the plants in this subfamily are characterized by having the seeds borne in a fleshy covering and having two to five carpels, or seed cavities, in each fruit. Within the Pomoideae the genus *Malus*,

comprising the apples, makes up one important group. Many botanists have included the apple in the pear genus, *Pyrus*. The fruits of these two groups are distinguished by the fact that the pears contain grit cells, while the flesh of the apple is free of grit cells. There are also other distinctive differences in the structure of certain flower parts.

The various species that make up the genus *Malus* can in most cases be hybridized rather readily. Species of *Malus* apparently do not hybridize readily with species of *Pyrus* or with those of other genera in the Pomoideae. No such crosses have been reported, although there has been ample opportunity for them to occur naturally in view of the wide distribution and adjacent plantings of many members of these genera.

There is some difference of opinion among botanists as to whether one or more than one species originally entered into the parentage of our cultivated apple. The wide diversity of existing forms has led some students to believe that several species were involved originally. However, this diversity might well be expected in a fruit crop selected and cultivated for thousands of years and propagated largely by vegetative means. Every interesting variation occurring in seedlings could thus be preserved.

In addition to the cultivated apple, Rehder, in his Manual of Cultivated Trees and Shrubs, lists 24 species of apples or crab apples, native mainly in China, Siberia, Japan, and the United States. Bailey in his Manual of Cultivated Plants makes a somewhat different division, listing 25 species of *Malus*. Knowledge of the close relatives that might be expected to hybridize readily with the cultivated apple is of much interest from the breeding standpoint.

While these species represent basic raw material available to the apple breeder, for most purposes it is not desirable to use the original types in breeding work. The selection of superior varieties through the centuries has given us breeding material that is far more promising than the parent species for the development of superior new kinds by hybridization. Only when special characters, such as extreme hardiness, are needed does it seem more desirable to use original species material. For the production of crab apple types and for ornamental purposes, however, these species are of outstanding value.

OBJECTIVES IN AMERICAN APPLE BREEDING

Objectives in the apple-breeding work vary, of course, in different sections. Throughout most of the apple belt in the United States increased winter hardiness is highly desirable, and in the colder sections, including the northern Great Plains area and northern New England, it is the all-important factor in apple production. A few varieties such as McIntosh, Wealthy, Oldenburg, and Yellow Transparent are sufficiently hardy for all but the northernmost part of the Plains region. Many important varieties, including Baldwin, Stayman Winesap, Winesap, Grimes Golden, Rome Beauty, Yellow Newtown, and Jonathan, may be severely injured or trees may be killed during severe winters in many sections of the country. Increased hardiness must continually be sought in the apple-breeding program for all but possibly the southeastern districts.

The second most important objective is greater disease resistance. The five diseases that cause the greatest loss of apples in the United States are scab, blotch, bitter rot, fire blight, and apple cedar rust. There are wide degrees of susceptibility to all of these diseases. No commercial variety is immune from scab. However, McIntosh, Delicious, Stayman Winesap, and Rome Beauty are far more subject to the disease than are Grimes Golden, York Imperial, Baldwin, or Jonathan. Similarly, Golden Delicious, Yellow Newtown, Grimes Golden, and Jonathan are extremely subject to bitter rot, and for this reason they are of doubtful value for planting in the far southeastern districts. On the other hand, Winesap, Baldwin, Delicious, Rome Beauty, Stayman Winesap, and York Imperial are relatively resistant to this disease.

Varieties very susceptible to blotch include Ben Davis, McIntosh, Northwestern Greening, and Oldenburg, while a list of relatively resistant varieties includes Delicious, Grimes Golden, Jonathan, Stayman Winesap, and York Imperial.

Baldwin and Delicious are highly resistant to apple cedar rust, while Jonathan, Rome Beauty, Wealthy, and York Imperial are quite susceptible. Seedlings of resistant parents show a high degree of resistance to this disease, while seedlings of susceptible parents are highly susceptible.

Fire blight is a serious orchard disease of Yellow Transparent, Jonathan, Wealthy, York Imperial, and a number of other varieties. On the other hand, Delicious, Ben Davis, and the Winesap family of varieties are resistant. We know that seedlings of Yellow Transparent tend to be susceptible, but we have little information as to how the characters of susceptibility or resistance to fire blight or other diseases behave in hybridization.

Susceptibility to spray injury also is an important character from the standpoint of evaluating a variety for commercial use. Golden Delicious and Ben Davis are particularly susceptible, while many varieties, including Delicious, McIntosh, Rhode Island Greening, Rome Beauty, Stayman Winesap, and others, show little injury.

The securing of new varieties fairly resistant to all of these diseases and to spray injury is a distinct possibility. It should be a primary objective in breeding, and all new selections should be studied from the standpoint of disease susceptibility.

The third objective, important in many parts of the United States, is the securing of late-blooming varieties that will have a greater possibility of escaping spring frosts and freezes. In most apple sections spring frosts or freezes are likely to reduce the apple crop greatly in certain years. In some sections this may run as high as 2 years in 5, in other sections perhaps not over 1 year in 10. Varieties blooming a week to 10 days later than standard types would have an increasingly better chance to escape such losses. This is particularly important in some of the midwestern areas. The late-blooming character is present in Rome Beauty, Mother, Ralls, and some other varieties, and through the use of such varieties in breeding, late-blooming trees can be obtained.

A fourth objective is the securing of varieties having highly developed, rich flavor combined with desirable tree characters.

Among highly flavored varieties are Delicious, Golden Delicious, Esopus Spitzenburg, Jonathan, Grimes Golden, and McIntosh. Many of these have horticultural weaknesses such as lack of hardiness, disease susceptibility, insufficient tree vigor, and susceptibility to spray injury.

It is desirable to obtain high-quality, attractively colored varieties that will be available throughout the year through the use of cold storage. Improvement in color in our present varieties is being accomplished by selection of attractive, highly colored bud mutations. On the average our long-keeping varieties are inferior in quality to those that are available earlier in the season, such as McIntosh, Grimes Golden, and Jonathan.

Another important objective is the development of varieties adapted to the far South. At present there are no satisfactory varieties for the region within 200 miles of the Gulf of Mexico. Native crab apples might be of value for hybridizing to produce varieties adapted to that region. No active work of this kind is under way, but there is a real need for it. Until apples can be grown locally, many people in that region will never have an adequate supply of the fruit.

The relative importance of these different objectives varies in different regions. In the Southeastern States disease resistance is of major importance. In the northern Plains area winter hardiness becomes the most important single objective. In the Missouri and Ohio Valleys, late blooming to escape the hazards of spring frost assumes major importance. Throughout all of the regions a succession of high-quality varieties available for use throughout the year is highly desirable.

METHODS OF IMPROVEMENT BY SELECTION OF BUD MUTATIONS

OCCASIONALLY cell division in the vegetative tissues fails to reproduce a new cell exactly like the parent. The result is an occasional branch or bud that varies in some respect from the parent tree on which it is borne. Such a mutant branch or bud normally reproduces true when propagated vegetatively, provided the variation is a true mutation and has not been caused by environmental conditions.

The fact that such bud or branch mutations occasionally occur has long been known to plant propagators. It is only in recent years, however, that the importance of these variations, from the standpoint of improving our fruit varieties, has been fully appreciated.

During the past decade an intensive search of American apple orchards has been conducted to locate such mutations as may be of value. Since red-colored apples command a considerable premium on the American markets, mutations carrying a greater amount of red color have been particularly sought. How successful the search has been is indicated by the fact that we now have more than 30 red strains of the Delicious variety. Many of these red strains, however, may prove to be so similar as to be practically indistinguishable. More than 15 red strains of Rome Beauty are known, 20 strains of Winesap, 8 strains of Stayman Winesap, and several strains of McIntosh, York Imperial, Jonathan, and other leading varieties. At the present time, strains believed to color earlier or to have better color are in existence

for practically all of the leading red or blushed apple varieties. In several varieties, namely, Delicious, Rome Beauty, Winesap, Jonathan, and Stayman Winesap, new commercial plantings are largely of the improved strains rather than the standard varietal forms.

It has been assumed by many nurserymen and growers that in general such mutations vary from the parent in only one character. This is not necessarily true. Variations in season of ripening, fruit size, storage quality, dessert quality, or productiveness may accompany color variations. Therefore the various bud mutations should be thoroughly tested before they are widely propagated commercially.

In addition to mutations affecting color, a few have been found that involve season of maturity, size, shape, and flavor of fruit. It is of course obvious that variations in flavor, storage quality, or productiveness are less likely to be located than are variations of color or season of maturity, which are very conspicuous when the fruit is still on the tree.

A search for bud mutations is especially likely to lead to rapid results in the improvement of horticultural varieties. Generally these mutations mean only a slight difference in varieties that have already proved themselves excellent from a commercial standpoint. For example, the Winesap apple is already established as a leading commercial variety. Its greatest weakness is its tendency to rather small fruit size and lack of tree vigor under all but the best soil conditions. Its growing season is too long to permit proper development of the fruit in northern districts. Thus, bud mutations of Winesap that would give an earlier ripening apple would extend the range northward. Similarly, a mutation showing larger size of fruit would be of much value. A search for such mutations should be continued in American orchards.

The process of selection, propagation, and testing of bud mutations perhaps offers a possibility for more rapid improvement of our present desirable varieties than does any other method of breeding. Possibly by bud selection we might find a later maturing McIntosh adapted for growing farther south than the present McIntosh belt, or an earlier maturing Stayman Winesap, Rome Beauty, or Winesap, which would mean better adaptation to northern sections. The fact that color can be improved by the use of such selections has already been amply demonstrated. The testing of bud mutations should be an integral part of the variety-improvement program in the years to come. For originating definitely new types of apples, however, or for the incorporation of new characters, such as greatly increased hardiness or vigor, hybridization appears to offer the greater possibilities.

HYBRIDIZATION OF APPLES. AND PEARS

There is no unusual difficulty in the technique of hybridizing apples and pears. Several steps of this technique are illustrated in figure 1. The flower parts of an apple or pear, in order, from the outside of the blossom to the center, are as follows: (1) The calyx, consisting of 5 sepals at the base of the blossom; (2), the corolla, made up of 5 white or pink petals; (3), the stamens or pollen-bearing organs, usually 20 in number, which are borne just inside the petals; (4), the pistil, the central organ that contains the seeds. In hybridizing most varieties

it is desirable to remove the pollen-bearing stamens from the flower before it opens. The best time to do this is at the so-called balloon stage, illustrated in figure 1, *A*, while the petals still form a complete covering over the inner flower parts. At that stage the stamens have not yet begun to shed pollen and there has previously been no opportunity for either self- or cross-pollination to occur.

Two methods may be employed in removing the pollen-bearing organs. In the method shown in the figure, the thumbnail or a small

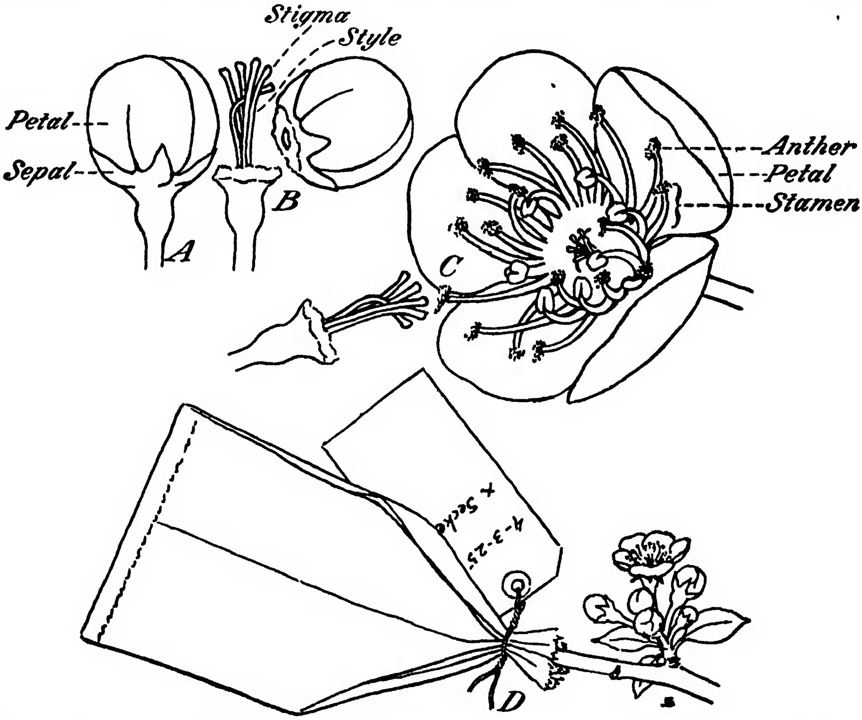

Figure 1.—**Steps in hybridization of apples and pears: *A*, Bud in proper stage for emasculation; *B*, after emasculation, showing petals, sepals, and stamens pinched off and removed; *C*, an open flower, showing the flower parts that are removed in emasculation; *D*, the method of protecting emasculated flowers from chance pollination.**

knife or a laboratory scalpel is used to make a cut just at the base of the sepals. The flower part is then bent sidewise, and the whole flower organ except the pistil can be torn loose, as shown in figure 1, *B*. If carefully done, this leaves the pistil, consisting of the ovary containing the seeds, with a cluster of styles and stigmas, as shown in *B*. The tearing loose of the flower parts may result in enough injury to reduce the set of fruit. In the second method, which is somewhat slower but less likely to cause injury, the petals are pulled loose at the stage shown in *A*, and the anthers are picked out of the blossom with an instrument; an ordinary comb is satisfactory.

If the flowers are within a day or two of opening when emasculated, it is satisfactory to apply the pollen of the selected male parent at the

time the emasculation is done; or the application of pollen may be postponed for a day or two. The pollen should be applied, however, before the stigmas begin to turn brown. The emasculated blossoms must be protected from chance pollination for several days. A satisfactory method is shown in figure 1, *D*.

A higher percentage of set of fruit will usually result if not more than two blossoms are emasculated and pollinated in a cluster. The remaining blossoms should, of course, be picked off at the time the emasculating is done.

Handling the Pollen

To secure pollen, buds in the stage shown in figure 1, *A*, are picked and the anthers combed out of them as described above. If these anthers are held in a moderately warm, dry place they will ripen rather rapidly and begin to shed pollen within 24 to 48 hours.

Sometimes branches of the desired pollen parent are brought into a room or a greenhouse before the blossoms open, set in water, and allowed to bloom protected from insects. The pollen is removed from the open flowers when it is ripe.

Pollen is usually applied to the stigmas of the emasculated blossoms with a fine camel's-hair brush, which may be sterilized between pollinations by washing in alcohol or immersing for several seconds in boiling water. After the pollen has been applied, the emasculated blossoms should again be protected (fig. 2). When conditions are favorable, from 30 to 50 percent of the emasculated blossoms should set fruit. After the stigmas have turned completely brown the protecting bags may be removed and labels designating the cross should be carefully adjusted. The fruit may be harvested when slightly immature to prevent undue loss from dropping. Germination of the seed is not affected by such early harvesting.

Handling the Fruit and Seeds

Two or three alternative methods may be used for handling the fruit and seeds after harvest. Since apple and pear seeds must go through certain transformations, often described as "resting" or "after ripening," before they will germinate, the fruit may be placed in cold or cellar storage and held until spring. The seeds can then be removed and immediately planted in nursery rows. An alternative method of handling is to remove the seed from the fruit after harvest, place it in small labeled bags, and put these in cold storage over winter. It is necessary that the seed be sufficiently well dried and that it be stored in a sufficiently dry place to prevent it from molding, but excessive drying should be avoided. A third method is to stratify or bury the seed and carry it over winter outdoors. If facilities are available, the seed may be planted in flats in the greenhouse or in coldframes and the seedlings allowed to grow 3 or 4 inches high before being transplanted to nursery rows in the field, but this is not necessary.

After 2 years in the nursery row the apple seedlings may be transplanted to the orchard, sufficient space being allowed to permit the trees to come into fruit. Pear trees can be planted at somewhat closer distances in the orchard than apple trees; they will usually fruit satisfactorily if planted about 4 feet apart in the row, with the rows

Figure 2.—Cross-pollinated apple blossoms protected under glassine bags and labeled.

about 15 feet apart to facilitate cultivation and spraying. Apple trees should have at least 10 feet of space in the row, with rows 15 feet apart, if the fruiting value of the young trees is to be adequately determined.

To speed up the testing and at the same time conserve space, buds or grafts from young seedling trees may be put into older trees growing in

orchard form. Several buds or grafts may be put into an apple tree 4 to 6 years old. Usually it is preferable to have only seedlings of the same parentage worked on one orchard tree. If such a tree is maintained in good vigor and if the budding or grafting is satisfactorily accomplished, fruiting records should be obtained within 3 to 4 years from the date of budding or grafting. Usually budwood or scions from the seedlings can be obtained at the end of the first growing season. Thus, by this method, an indication of fruit value with apples or pears can be obtained in about 5 years from the time of making the cross. If the seedlings themselves are grown to fruiting age in the orchard, 8 to 10 years will usually be required. However, growing the seedling itself to fruiting permits a better evaluation of the tree from the standpoint of vigor, hardiness, disease resistance, and tree form.

In using the budding or grafting method, it is desirable to have trees that are not too old. Young orchard trees 4 to 5 years old are most nearly ideal from the standpoint of top-working, and they are small enough to facilitate the work of taking records on fruiting branches.

Several steps in apple breeding as carried on at the New York Agricultural Experiment Station at Geneva are illustrated in figures 3, 4, and 5.[3]

Significance of Unusual Chromosome Numbers

It is only within the last 10 years that we have had definite information on the chromosome numbers of the various apple varieties. This has clarified our understanding of the behavior of varieties, particularly from the standpoint of pollination and breeding. We now understand the reasons for the peculiar behavior of certain varieties long observed in the orchard.

Investigators have known for some years that certain varieties are poor pollinizers for others. They do not form much good pollen, most of the grains being abortive and failing to grow when put in a sugar solution suitable for pollen germination. Usually when these varieties are planted alone or in blocks with others of similar type, poor sets of fruit are secured. Among the varieties known as poor pollinizers are Stayman Winesap, Baldwin, Rhode Island Greening, Gravenstein, Arkansas (Black Twig), Tompkins King, Stark, and several less important ones.

These varieties have certain other characteristics in common also. All produce large-sized fruit, and all are vigorous growers and develop into large trees. Nursery investigations have indicated that as a rule seed produced by these varieties germinates poorly and the seedling trees are usually weak growers.

Our present knowledge of the number of chromosomes in apple varieties has been contributed by many investigators in many countries, including V. A. Rybin, in the Union of Soviet Socialist Republics; A. A. Moffett, M. B. Crane, W. J. C. Lawrence, and C. D. Darlington, in England; J. S. Shoemaker and B. R. Nebel, in the United States; F. Kobel, in Germany; O. Heilborn, in Sweden; and others. These workers have shown that most of the cultivated varieties of apples have 34 chromosomes (17 pairs) in the vegetative or somatic tissues, and 17 (one member of each pair) in the germ cells. These varieties

with 34 diploid chromosomes as a rule produce fertile pollen and they are generally classed as good pollinizers for other varieties. The trees vary in vigor from low to moderately high, and fruit size varies from small to large.

The peculiarity of the second group of varieties, described above as being partially or in some cases almost entirely pollen-sterile and

Figure 5.—Second tests of promising hybrid selections. The tree in the foreground is Early McIntosh.

producing large fruit and large vigorous trees, is that they have 51 chromosomes instead of 34 in the somatic tissues. They are termed triploids,[4] since the chromosome number in the vegetative tissue is three times that of the usual reproductive cells of apples, instead of twice, as in the diploids.

[4] This is discussed by A. F. Blakeslee in his article in this Yearbook.

The question arises, How have these triploid varieties developed? Normally the cells of the vegetative tissue have only twice as many chromosomes as the reproductive cells. How can we account for the considerable number of apple varieties that carry three times this basic chromosome number?

It is not known definitely how the triploid forms developed. At long intervals, the frequency varying with different species, a germ cell in either the male or the female organs may be developed with an extra set of chromosomes. Experimentally, cells are occasionally formed with double the normal number of chromosomes as a result of subjecting them during the process of germ-cell formation to unusual environmental conditions, such as high or low temperatures. It may be deduced, therefore, that at rare intervals under natural conditions pollen grains or egg cells are formed that carry 34 rather than 17 chromosomes in the reproductive cells.

Now if an egg cell carrying 34 chromosomes is fertilized by a sperm carrying 17 chromosomes, the resulting fertilized egg will have 51 chromosomes. It will develop into an embryo and ultimately into a plant carrying 51 chromosomes in its vegetative tissues. If such a tree is propagated vegetatively, the result is a horticultural variety with 51 chromosomes instead of the normal 34.

Approximately one-fourth of all commercial apple varieties are these triploid or 51-chromosome forms. Yet it is probable that such forms are rarely produced among seedling apple trees. For example, in all of the controlled breeding work that has been done in the United States, involving crosses of diploid × diploid, diploid × triploid, triploid × diploid, and triploid × triploid, no seedling of merit known to be a triploid has been produced. It is apparent, therefore, that in nature triploid forms are produced only rarely as compared to diploids.

How, then, can we account for the fact that at least a fourth of our important varieties are triploids? This is possible only if we assume that the triploids have characteristics that make them of unusual value as commercial varieties, so that an unusually high proportion of the triploid forms have been selected and propagated as varieties. It is probable that in the United States in the last 250 years more than 200,000,000 apple trees of seedling origin have grown and fruited. Even if only 1 in 50,000 of these was a triploid, it would mean that several thousand triploid trees have grown in the United States some time during the past two and a half centuries. If these trees on the average had certain superior characteristics as compared with the hundreds of millions of diploid trees, they could easily have become the source of a relatively large number of improved varieties. Some of their characteristics of unusual value from a commercial standpoint have already been enumerated, namely, large size of fruit and vigorous growth and large size of trees. Heilborn (*9*) has also pointed out that most of the triploid varieties grown in Europe have relatively long storage quality. This does not apply to all of the American triploid varieties, but many of them are firm-fleshed apples of good storage quality. Thus it seems probable that from the mass of seedling material available in the United States and Europe a relatively high proportion of the rare triploids has been selected and a relatively small proportion of the more common diploids.

Can We Breed for Triploid Varieties?

These points of superiority of the triploid varieties would indicate that attempts should be made to secure triploids in breeding. It is true that a large portion of the seedlings produced in breeding work tend to run to medium or small fruit size. This tendency could undoubtedly be corrected if triploid varieties could be obtained at will. Unfortunately, however, this cannot be done.

As explained above, crossing of diploid × diploid varieties normally gives only diploids. What occurs when we cross diploids × triploids or triploids × triploids?

The triploid somatic or vegetative cells contain 51 chromosomes—34 obtained from one parent germ cell and 17 from the other. In the pairing of the chromosomes, which takes place prior to the formation of germ cells, 34 will pair normally into 17 pairs. But the remaining 17 of the 51 chromosomes are not arranged in any special order, and they are unable to pair among themselves. After pairing, the chromosomes again divide, half going to one pole of the nucleus and half to the other pole. But the 17 unpaired chromosomes cannot do this in an orderly fashion. Some of them go to one pole and some to the other at random. Thus, when the cell finally splits in half to form two germ cells, we find that each of these contains 17 chromosomes from the original pairs and an indefinite number of other chromosomes from those that had not paired. This indefinite number varies all the way from none at all to the whole 17 unpaired chromosomes. Such a germ cell may have any number of chromosomes from 17 to 34.

The great majority of these germ cells with an irregular chromosome number are sterile. The addition of chromosomes above the normal number but less than double the number seems to result in sterility to a large extent throughout the plant kingdom. In apples, however, some viable pollen grains are found in most of the triploid forms, and in most varieties enough of the egg cells are sufficiently fertile to give a satisfactory fruit set, particularly if they are pollinated with diploid pollen.

However, when the egg cell containing 17 to 34 chromosomes is fertilized with a nucleus from diploid pollen containing 17 chromosomes, we usually will have neither diploid nor triploid offspring. The number will vary from 34 to 51, that is, 17 from the pollen cell plus 17 to 34 from the egg cell. These are called aneuploids, and the seeds generally germinate poorly. Those that do grow are likely to produce weak seedlings, though occasionally they are fairly vigorous. It is of interest to note, however, that of the varieties that have been introduced as a result of breeding work in the United States to date, none has a parent of known triploid constitution. This is in line with cytological studies on many species of plants, which indicate the slight probability of obtaining promising varieties when one or both of the parents are triploids.

Triploids crossed with triploids also are likely to give aneuploid progeny. Here the possible number of chromosomes will range from 34 to 68 and may be expressed numerically by the formula $[17+(0\text{ to }17)]+[17+(0\text{ to }17)]$. Such triploid × triploid progeny are likely to be weak vegetatively if they grow at all.

In order to obtain triploids at will in breeding, it is necessary to have a tetraploid parent (four times the basic number) to cross with a diploid. We do not now have any apple or pear varieties that are known to be tetraploids. There is a possibility that tetraploids resulting from chromosome doubling in some cell in the vegetative tissues originate at rare intervals as bud sports or somatic mutations in normal diploid varieties. One or two mutations that may be of this type have recently been found in pears, though their nature has not yet been definitely determined. If similar mutations can be found in apples, they will be of great interest from the breeding standpoint. Such bud sports will probably be characterized by giant fruits, since the character of giantism is often associated with chromosome doubling. Giant strains of apples, occurring as bud sports, should be carefully preserved until their character can be determined, even though the fruit itself may appear to be of no value.

Aside from diploid and triploid varieties, a word should be said as to the chromosome make-up of the genera *Malus* and *Pyrus*. These genera and other closely related forms stand out among the Rosaceae in having 17 chromosomes in the reduced phase (the reproductive cells), whereas the basic number in other genera of the family is mostly 7 and in a few 8 or 9. In *Malus* and *Pyrus* the 17 chromosomes are believed to represent multiplication from the simpler base of 7, 8, or 9, either by hybridization or by polyploid mutations. This complex chromosome constitution of apples and pears may account for the fact that there is such wide variation in selected varieties within these species, that mutations both in seed reproduction and vegetative tissues occur fairly frequently, and that most selected varieties are highly heterozygous, failing to reproduce seedlings closely resembling the parent.

INHERITANCE OF TREE AND FRUIT CHARACTERS

Most of our apple varieties are highly heterozygous, or mixed in their inheritance. This fact, coupled with the long time required to grow a generation, the impossibility of successfully selfing most varieties, and the relatively small populations that can be grown, makes the working out of inheritance factors difficult. The following summation is taken mainly from Wellington (*17*), Auchter (*2*), Lantz and Bole (*12*), and Crane and Lawrence (*6*).

Triploid × triploid or triploid × diploid varieties produce generally weak trees if seeds grow, because of aneuploid chromosome make-up.

Among diploid × diploid crosses, weak growth appears recessive to vigorous growth.

Tree shape—spreading, round, or upright—appears to be due to a number of genes. Forms of hybrids are usually intermediate between parents, with the progeny tending to be more nearly round than a strictly intermediate form would be.

Age of bearing is undoubtedly inherited, but simple segregations have not been obtained. Late-bearing and early-bearing parents tend to transmit these tendencies.

Susceptibility to apple cedar rust, to blight, and to scab appears to be inherited, but little is known of the segregations involved.

Date of fruit ripening follows parent behavior closely. Late-ripening parents give late-ripening progeny; early-ripening parents, early-ripening progeny; and early × late crosses usually ripen between the ripening dates of the two parents. In fruit size, large size seems dominant over small, but the factors are complex. Small crab apples crossed with apples give intermediate sizes. Most large apples carry some factors for small. To secure large size, cross large × large. Large × small fruit sizes yield progenies that are usually intermediate. Crane and Lawrence found the average of the progeny to be somewhat smaller than the average of the two parents.

Yellow or green skin color usually behaves as a recessive, though occasional red apples will appear in yellow × yellow hybrids. Apparently a number of factors are involved in color. Blush × blush parents may occasionally give deeper reds than either parent.

Flesh texture appears to follow parent type to a considerable degree, but some coarse-fleshed progeny are produced by tender-fleshed parents. Several factors appear to be involved in flesh texture, as well as in flesh color.

In flavor, sweet (lack of acidity) appears to be recessive. Some highly acid varieties, as Boiken, Oldenburg, and Montgomery, seem to be homozygous, or "pure" in their inheritance, for acidity. Mildly acid varieties give some sweet progeny and appear heterozygous for sweetness. Acid × acid gives a considerable proportion of progeny with acidity accentuated beyond either parent.

APPLE BREEDING IN THE UNITED STATES

A RELATIVELY large program of apple breeding is now under way in the United States, with active projects at 12 experiment stations and work at two points by the United States Department of Agriculture. The past and present workers in apple breeding are listed in the appendix. (See table 4.) In table 3 are summarized the crosses made at the stations that have fruited to date, together with the number of progeny from each cross considered to have horticultural promise, either as varieties or for further breeding work.

In the following pages, the work at the various stations is briefly summarized.

IDAHO

At the Idaho Agricultural Experiment Station, Moscow, breeding was begun in 1909 by C. C. Vincent, and since then 11,824 hybrid seedlings have been planted in orchard form . Results have indicated that the Jonathan, Wagener, and Esopus Spitzenburg varieties have tended to give highest dessert quality. Ben Davis crosses have the highest percentage of seedlings showing good keeping quality. No varieties have yet been introduced to the trade, but 101 selections have been made for detailed study.

ILLINOIS

Since the work was started at the Illinois Agricultural Experiment Station, Urbana, in 1908 by C. S. Crandall, approximately 15,000 trees have been fruited in the orchard, and detailed records have been made of the characteristics of the fruit produced. In the earlier work, a large number of crosses were made between cultivated varieties and

various species of crab apples. Later, the emphasis has shifted to hybridizing commercial varieties containing the qualities desired. The primary objective in the early breeding work was to secure data on genetic behavior of the apple. This is being continued, but greater emphasis is now placed on the securing of high dessert quality and good keeping quality in new varieties. At the present time, almost 3,000 seedlings representing high-quality parents are being grown. The principal varieties used in this later breeding work include Akin, Delicious, Jonathan, Golden Delicious, Maiden Blush, Fameuse, Winesap, Fanny, Grimes Golden, and Rome Beauty. In breeding for early apples of good quality, Yellow Transparent is being crossed with high-quality standard-season varieties.

From the seedlings that have fruited, 338 promising selections are being held for further observation as to their commercial value No varieties have been named.

Iowa

Apple-breeding work in Iowa was begun by C. G. Patten (fig. 6) at Charles City about 1867. Patten began as an independent fruit breeder but later received some financial assistance from the Iowa State Horticultural Society. From 1909 to 1914 the United States Department of Agriculture assisted in the work. In 1916 the State purchased the farm and fruit-breeding materials and the station was operated by the Iowa Agricultural Experiment Station until 1932. Patten introduced several varieties—Patten, Eastman, Brilliant, Silas Wilson, Iowa Beauty, and University. A number of selections from his work are still being used by the Iowa station.

Figure 6.—Charles G. Patten (1832–1921), a pioneer breeder of hardy apples, pears, and plums at Charles City, Iowa.

Work in fruit breeding and variety testing was begun at the Iowa Agricultural Experiment Station, Ames, about 1880, by J. L. Budd. The primary objective was to secure varieties of fairly good quality that would be hardy and productive under the severe winter conditions existing in Iowa. A large number of Russian varieties were introduced between 1880 and 1890 and tested at Ames. Most of these were not of desirable quality although many were extremely hardy. The inherent hardiness of this group of apples suggested their value for breeding. That they transmit their hardiness to their seedlings has been amply demonstrated by the work at the Iowa station since 1917. Budd grew seedlings of many open-pollinated fruits during the period from 1882 to 1905. Fruiting records were not made, and the results of this earlier work are not available. In general, results were

not sufficiently good to warrant continued work with open-pollinated seedlings.

The cross-breeding work in apples was initiated by S. A. Beach (fig. 7) in 1905, and large numbers of crosses were made between 1906 and 1910. Further breeding work was not attempted until the crosses were fruited. The seedlings began to fruit in 1916 and were described and the results tabulated by H. L. Lantz, T. J. Maney, and others, under the direction of Beach.

Figure 7.—Spencer Ambrose Beach (1862–1922). As head of the horticultural work at the New York (State) Agricultural Experiment Station from 1891 to 1905, and at the Iowa Agricultural Experiment Station from 1905 to 1922, he laid sure foundations for the splendid work of both stations in the breeding of fruit crops.

In an effort to bring the seedling trees into fruiting as early as possible, top-working was practiced, with three to five different seedlings worked on suitable stocks. While top-working was found to promote earlier bearing, several difficulties developed. Some scions failed to make satisfactory growth because they were too heavily shaded by more vigorous neighbors. Records were difficult to make because of confusion as to location of each graft on the tree. The growth habit of the tree could not be satisfactorily determined on top-worked material. In later work, therefore, the practice of top-working was discontinued. The varieties that have been introduced to date as a result of the breeding work at the Iowa station are listed in table 2 in the appendix.

After most of the crosses made by Beach had fruited, additional crossing was started and has been carried on with little interruption. At the present time, about 13,000 seedlings are being grown to fruiting from crosses made since 1917. A considerable number of these are now fruiting. A summary of the parentage of these seedlings is published in the Transactions of the Iowa State Horticultural Society, 1935.

Maine

Breeding work was begun at the Maine Agricultural Experiment Station, Orono, in 1911, but no records of the earlier work are available. Approximately 1,000 seedlings of crosses of McIntosh, Golden Delicious, Delicious, Northern Spy, Wealthy, and Cortland are now growing in nursery rows. Additional crosses involving the above varieties and Haralson and Scott Winter have been made during the past year. The objectives in this work are to secure hardy, high-quality varieties adapted to New England.

Chromosome counts have been made on several apple varieties. The following apparently are diploids: Ben Davis, Oldenburg, Early Harvest, Golden Delicious, LaRue, McIntosh, Milden, Northern Spy, Opalescent, Porter, Red Astrachan, Golden Russet, Chenango, Tolman Sweet, Wealthy, Wolf River, and Yellow Transparent. Varieties showing irregular chromosome numbers, probably triploids,

Figure 8.—The fruits of breeding: Apple orchards in the Shenandoah-Potomac Valley section.

include Baldwin, Gravenstein, Rhode Island Greening, Rolfe, and Stark.

Maryland

Breeding work at the University of Maryland, College Park, was started in 1906. The objective at first was to produce early-ripening red varieties of good quality. A total of 1,073 seedlings were grown prior to 1917. In this group of seedlings, 13 were selected as promising.

Since 1929, a limited number of seedlings have been grown as a result of seed produced in pollination work. Three hundred and fifty-eight seedlings, representing crosses of good-quality main-season varieties, are now growing in the experimental orchard. Typical western Maryland apple orchards are shown in figure 8.

Massachusetts

At the Massachusetts Agricultural Experiment Station, Amherst, a number of cross-pollinated seeds resulting from pollination work have been planted from 1925 to date. These include crosses of Red

Astrachan with Cortland, Delicious, and McIntosh; McIntosh with Cortland, Delicious, Northern Spy, and Macoun; Northern Spy with Delicious, McIntosh, and Wealthy; Gravenstein with Wealthy; and Northern Spy selfed.

Minnesota

Apple-breeding work supported by the State of Minnesota was started in 1878, when an annual subsidy administered by the board of regents of the university was granted to Peter Gideon for continuation of his breeding work. Apple breeding organized by and completely under the control of the Minnesota Agricultural Experiment Station was begun about 1890, under the direction of S. B. Green. From 1890 to 1905 several thousand seedlings, largely of Russian varieties, were grown. In 1907 about 4,000 seedlings of Malinda, open pollinated, were planted in the field. About 300 of these have characteristics either of hardiness or fruit quality of sufficient merit to be retained.

From 1907 to 1912 approximately 13,000 seedlings, many from controlled crosses, were grown. In this group of material, 541 trees have been retained for further study. Since 1918, 4,781 seedling trees of hybrid parentage have been grown to fruiting in the breeding plots. The principal crosses are listed in table 3 in the appendix. At the present time, approximately 5,000 trees resulting from crosses made from 1921 to date are being grown to fruiting.

The primary objective in Minnesota is the securing of varieties of good quality that are hardy under the extremely cold winters of that section. Several varieties introduced as a result of the breeding work are listed in table 2, in the appendix.

During the past 100 years a number of individuals have contributed to the list of hardy varieties adapted to this section. The best known of these, Peter Gideon, began planting seed in 1854. He introduced the Wealthy, still one of the leading apple varieties of the United States. Peter, Gideon, and Gideon Sweet were other varieties developed by him. Others in the State who have raised apple seedlings for the specific purpose of developing hardy varieties include G. H. Pond, of Bloomington; John Shaw, of Minnesota City; H. M. Lyman, of Excelsior; Amasa Stewart, of Le Sueur County; Titus Day, of Farmington; Henry Stubbs; and others. A relatively large number of hardy apples have been named as the result of the efforts of these men.

Missouri

Apple-breeding investigations in Missouri are conducted both at the Missouri State Fruit Experiment Station, Mountain Grove, and at the University of Missouri, Columbia. Work at Mountain Grove was started in 1901. In 1935 the six varieties listed in table 2 were introduced.

The primary objective in the early breeding work at the Mountain Grove station was to obtain good storage varieties well adapted to growing conditions in Missouri. With this objective, the principal varieties used included Ben Davis, Winesap, Jonathan, Ingram, and Delicious.

In the breeding work since 1923, the primary objective has been to produce late-blooming varieties with high quality. The principal varieties used include Ralls, Ingram, Mother, Northern Spy, Jona-

than, Delicious, King David, and Golden Delicious. Since 1923, 1,821 seedlings of known parentage have been produced and are now growing in orchard form. Most of these have not yet fruited.

At the University of Missouri, at Columbia, some apple-breeding work has been conducted since 1905. The variety Whitten, from an Ingram × Delicious cross made in 1905 by J. C. Whitten, was introduced in 1925. This is a vigorous tree, a prolific bearer, and has fruit above medium size, yellow blushed with red, and of good quality.

At the present time, 2,732 seedlings resulting from crosses made in 1931 and 1932 at the State Fruit Experiment Station are being grown to fruiting at Columbia. This collection consists mainly of crosses of King David, Wolf River, Ingram, Alexander, Ralls, Twenty Ounce, Rome Beauty, Jonathan, Golden Delicious, Delicious, Mother, Gravenstein, and Northern Spy.

New York

Breeding work with apples at the New York (State) Agricultural Experiment Station, Geneva, was started in 1892, and since that time over 13,000 apple seedlings have been set in the orchard for fruiting, with nearly 2,000 additional now in the nurseries. Over 9,000 of these trees have been set in the orchard since 1922, so the major part of the seedlings have not yet been tested. In producing these 15,000 seedlings, 110 varieties, 10 species, and 63 seedlings have been used as parents. Fifty-five varieties and seedlings have been self-pollinated, but seedlings resulting from these self-pollinations have lacked vigor. Varieties now known to be triploids, including Baldwin, Gravenstein, Rhode Island Greening, and Tompkins King, have given only weak and worthless progeny. Of the diploid varieties, crosses of McIntosh have given by far the greatest number of desirable seedlings. Crosses of Northern Spy and of Yellow Newtown generally produce late-maturing fruit. Yellow Transparent has given early-ripening varieties tart in flavor. Delicious and Deacon Jones have given mostly mild-flavored fruits. Results show that if large-fruited seedlings are desired, large-fruited parents must be used. Sweet flavor appears to behave as recessive, but it is usually impossible to predict just how flavors will be transmitted.

Varieties used most extensively in the breeding work are: Baldwin, 23 times; Cortland, 71; Deacon Jones, 26; Delicious, 38; Early McIntosh, 41; Gravenstein, including Red Gravenstein, 27; Kendall, 26; Macoun, 37; McIntosh, 186; Milton, 31; Northern Spy and Red Spy, 76; Oldenburg, including red sports, 39; Rhode Island Greening, 27; Rome Beauty, including red sports, 57; Wealthy, 32; Yellow Newtown, 30; and Yellow Transparent, 35.

The specific objective of the New York station is to obtain hardy, good-quality apples for dessert and cooking that ripen throughout the season. The most important single need is to secure a high-quality, productive, late-keeping red variety that is fully hardy under New York State conditions. Tree characters desired include early bearing, hardiness to cold winters, self-fruitfulness, sufficiently late blooming to resist spring frosts, and resistance to insects and diseases.

A study of the chromosome constitution of varieties and seedlings is an important part of the breeding program. Crossing of triploid

varieties or of triploid and diploid varieties has produced no new triploid varieties. Chromosome counts on more than 100 resulting seedlings have been made, and all have been aneuploids; that is, having chromosome numbers other than 34 or 51. More than 1,000 such seedlings have been discarded for lack of vigor and fertility. Table 2, in the appendix, lists the varieties introduced as a result of the breeding work at the Geneva station.

There is no formal breeding project at the New York (Cornell) station, Ithaca. At present, about 100 seedling trees of McIntosh crosses, obtained incidentally in pollination experiments, are being grown to fruiting.

Ohio

Apple-breeding work was begun at the Ohio Agricultural Experiment Station, Wooster, by J. B. Keil in 1915. During that year and the year following, crosses were made from which 963 seedlings have fruited. Of these, 25 have been selected for further study or for further use in breeding.

Since 1929, some additional crosses have been made each year by F. S. Howlett and C. W. Ellenwood. From these, 2,414 seedlings are now being grown to fruiting. These later crosses are primarily between Delicious, McIntosh, Gallia Beauty, Northern Spy, Golden Delicious, Cox Orange, Jonathan, Esopus Spitzenburg, Ralls, Rome Beauty, Mother, and some of the numbered selections that resulted from the earlier breeding work. Table 2 in the appendix lists five varieties recently introduced as a result of the breeding work in Ohio.

The specific objectives include (1) to obtain late-blooming varieties that will thus tend to escape the hazards of spring frosts and freezes, and (2) to develop late-keeping varieties whose storage season will extend from February until late spring. A considerable number of seedlings that bloom later than Rome Beauty and Northern Spy, but for the most part derived from these two varieties, have been obtained.

South Dakota

Breeding of apples and other hardy fruits has been a leading horticultural project at the South Dakota Agricultural Experiment Station, Brookings, since 1895. The primary objective is to obtain fruits of fair to good quality that are hardy under the extreme winter cold and frequent summer drought of the northern Plains area. Fully 10,000 apple seedlings of various pedigrees have been grown to fruiting. Much of this has been open-pollinated material. Numerous hybrids between selections of wild crab apples and hardy cultivated apple varieties have been made. As a result of this breeding work, about 25 varieties of crab apples and a considerable number of apples have been introduced. The apples, with their parentage and characteristics, are listed in table 2, in the appendix. Crab apples introduced include Alexis, Amur, Cathay, Beauty, Dolgo, Hopa, Ivan, Izo, Kola, Linda, Maga, Mercer, Missouri Pippin, Nocalyx, Olga, Red Tip, Sapinia, Shoko, Sugar, Tipi, Zapta, Red Flesh, Wakonda, Zelma, Zita, Zaza, Bison, Caputa, Wanblee, Waubay, and Amsib.

Virginia

The apple-breeding program at the Virginia Agricultural Experiment Station, Blacksburg, is not extensive. A number of open-pollinated seedlings have been fruited, of which one from Mother, one from Northern Spy, and three from Delicious appear to have horticultural value. A number of crosses are being made to secure late-blooming, high-quality, and highly colored varieties. Eight hundred fifty-six seedlings of Ralls × Rome Beauty, 622 seedlings of Ralls × Mother, and 1,234 seedlings of York Imperial open-pollinated are now growing in the nursery row.

United States Department of Agriculture

A limited amount of apple breeding has been done by Department of Agriculture workers. From 1912 to 1920, C. P. Close hybridized early varieties with the objective of securing early good-quality varieties in season with Yellow Transparent, or before, and preferably carrying red color. The varieties used included Yellow Transparent, Early Harvest, Early Ripe, Red June, and Red Astrachan. About 400 seedlings representing hybrids of these varieties have fruited in the orchard.

A number of early-ripening selections have been made. Seven of these selections, carrying red color and ripening with Yellow Transparent or earlier, have been distributed for experimental testing. Yellow Transparent has tended to be an excellent parent in the transmission of shape, size, and season of ripening.

Approximately 500 seedling trees of crosses made from 1927 to 1929 are now coming into fruiting at the National Agricultural Research Center, Beltsville, Md. These represent crosses of long-keeping varieties made with the objective of securing good-quality, long storage-season types. The principal parents include Winesap, Yellow Newtown, Granny Smith, Vandervere, and McIntosh.

Promising bud mutations of possible horticultural value originating in various parts of the United States are being grown for comparative testing at Beltsville. The oldest of these selections have now been planted in the orchard 4 years. Additional plantings have been made each year as additional material has been collected. Four trees propagated from each mutation are grown in comparison with parent varieties. In the orchard at the present time are the following bud sports: Baldwin 3, Delicious 30, Gravenstein 5, Jonathan 4, McIntosh 4, Northern Spy 3, Oldenburg 5, Rome Beauty 15, Stark 2, Stayman Winesap 9, St. Lawrence 1, Summer Queen 1, Twenty Ounce 1, Willowtwig 1, and Winesap 20.

Work to develop hardier and better fruits for the northern Great Plains area has been in progress at the United States Northern Great Plains Field Station, near Mandan, N. Dak., since 1915. A large number of Wealthy and other apple and crab apple seedlings have been grown. Several selections from these have been propagated and are being given further test. None has as yet been named. This method of growing quantities of apple seedlings of unknown or partially unknown parentage has been discontinued during recent years, and seedlings of known parentage are being produced at the

present time. About 10,000 apple trees of known parentage are now growing, but only a small part of these have reached bearing age.

A considerable amount of hybridizing between the Siberian crab, *Malus baccata* (L.) Borkh., and standard apple varieties was done in earlier years. These crosses have resulted in seedlings that are hardy and vigorous but have generally small fruits. The varieties being used most largely for hybridizing purposes include Wealthy, Oldenburg, Red Duchess, McIntosh, Delicious, Starking, Yellow Transparent, Haralson, Anoka, and the crab apples Dolgo, Florence, and Whitney.

APPLE BREEDING IN CANADA

Beginning in 1889, a major program was started to develop superior apple varieties sufficiently hardy to withstand rigorous weather conditions in all parts of Canada. At the Central Experimental Farm, Ottawa, seed of Russian varieties planted in 1889 gave 3,000 trees. From this work, only one variety worthy of mention developed—the Rupert, an apple a little earlier than Yellow Transparent and equal to it in quality.

The next step was the crossing of the Siberian crab with named Russian and American apple varieties. Fruits of the first-generation progeny were all under 2 inches in diameter. These, recrossed with apple varieties, gave fruits up to 2½ inches in diameter but lost some of the hardiness of the first-generation hybrids. Most of the fruit of the first-generation hybrids retained the crab characters—long, slender stem; thin, tender skin; and firm, crisp, breaking flesh.

Cross-breeding with better varieties was begun in 1898. Since then, 253 different combinations with 66 different varieties have been made. The variety that has been outstanding as a parent is McIntosh. In one block of 159 trees from open-pollinated McIntosh seed saved in 1898, 27 varieties of sufficient promise for naming were developed. Among these are Melba, Joyce, Macross, Hume, and Lobo. In more recent years, McIntosh has been crossed with the finest quality varieties available. Much of this material has not yet fruited.

In addition to this work carried on at the Central Experimental Farm, breeding is also conducted at the Ontario Agricultural College, Guelph, Ontario, and at the Horticultural Experiment Station, Vineland, Ontario. At Guelph, several thousand seedlings, representing mainly crosses of the McIntosh, Northern Spy, Wealthy, Wagener, and several other varieties, have been fruited. At Vineland, more than 8,000 seedlings have been grown since the work was started in 1915. These represent 130 crosses between varieties, and seed of 65 crosses and selections open-pollinated.

In more recent years the attempts to secure extreme hardiness have been centered at experiment stations in the prairie Provinces, namely, the University of Saskatchewan, Saskatoon, Saskatchewan, and the Dominion Experimental Station at Morden, Manitoba. The most extensive project is at the University of Saskatchewan. Prior to 1930, more than a quarter of a million crosses of apples had been made at that place. The female parents used have been the Siberian crab and the hardiest of the hybrid crab apples such as Osman, Co-

lumbia, Prince, Charles, Tony, and Magnus. The apple varieties have included McIntosh, Melba, Wealthy, Oldenburg, St. Lawrence, and Yellow Transparent.

The largest collection in Canada of the hardiest varieties of apples and crab apples is at the Dominion Experimental Station at Morden. In 1916 some 27,000 open-pollinated seedlings from the hardiest Russian and other varieties of apples were planted. Several thousand of these have fruited, and many are being tested in the prairie Provinces.

A limited amount of breeding work is under way at the Dominion Experimental Station, Summerland, British Columbia. This work consists of crosses of high-quality and long-storage apples. The principal parents used are McIntosh, Yellow Newtown, Winesap, Delicious, Golden Delicious, Rome Beauty, and Grimes Golden. The earliest of these seedlings are just coming into fruiting. Macoun summarized the first 40 years of apple-breeding work in Canada, with the comment that the time should not be far distant when there will be varieties of Canadian apples suitable for all parts of that country where farm development is possible. Experience with breeding apples in Canada indicates the following conclusions, according to Macoun (*13*):

(1) To originate extremely hardy apples:
(a) Cross the apple with the wild Siberian crab and recross the hardiest F_1 with the apple.
(b) Sow seeds of apples that are hardy in other sections having severe climatic conditions.

(2) To originate apples having hardiness, vigor, productiveness of tree, and high quality, good size, and appearance, cross varieties having most of the characteristics desired.

(3) In cross-breeding, where quality is an important factor, cross two varieties that are both good or very good in quality. In crossing a variety of good quality with one of inferior quality, the F_1 will nearly always bear fruit of mediocre quality.

(4) Use parents that have been found by other breeders to transmit their desirable characters to a large degree.

APPLE BREEDING IN EUROPE

The work of European agencies in apple breeding is summarized in the appendix. This summary includes work with the other tree fruits as well as apples, since in most cases several fruits are involved in a single more or less unified breeding program.

APPENDIX

The following summary includes the more important fruit-breeding stations in Europe.

Czechoslovakia

Průhonice; State Institute for Horticultural Research (director, Ing. Fr. Landovský; chief, Division of Fruit Trees and Nurseries, Ing. J. Souček).—Objective: To secure fruits of better quality with good storage and utilization properties.

Lednice, Morava; Fürst Liechtenstein Plant-Breeding Institute (director, Prof. Dr. Fr. Frimmel).—Extensive breeding investigations of apples and peaches are being conducted. Crosses of several apple varieties are at fruiting age and are being tested in comparison with standard varieties.

England

Long Ashton: Agricultural and Horticultural Research Station, University of Bristol (director, Prof. B. T. P. Barker).—In connection with general fruit investigations, the station conducts breeding investigations on apples, pears, plums, and berries. Several apple varieties, one pear, and four plums have been named and distributed. The objective in the breeding work is to produce high-quality dessert varieties.

East Malling, Kent; Horticultural Research Station (director, R. G. Hatton).—Breeding investigations include the following principal lines:

(1) *Apples*.—Production of rootstocks immune to woolly aphis and conferring disease resistance on the scions; production of fruiting varieties resistant to woolly aphis; production of commercial varieties ripening at times when present English varieties are not available.

(2) *Plums.*—Production of new varieties of rootstock that propagate readily and confer resistance to silver leaf and to bacterial dieback diseases.

(3) *Pears.*—Production of improved varieties of quince stock compatible with pear varieties, and production of commercial pear varieties of high quality.

Merton; John Innes Horticultural Institution (director, Sir Daniel Hall).—The institution is engaged primarily in genetic and cytological research from the standpoint of pure science. When the investigations on inheritance in fruit produce varieties of promise for commercial cultivation, they are selected and given an extended try-out.

(1) *Apples.*—Four thousand seedlings and varieties provide data for the study of the inheritance of characters. About 40 are under extended tests as market varieties. Breeding of rootstocks resistant to woolly aphis, carried on in collaboration with the East Malling station, has yielded seedlings of promise now under trial.

(2) *Plums.*—A large number of seedling plums are being grown in the study of inheritance of characters, particularly of self-incompatibility. Selected seedlings are under trial for commercial value.

(3) *Cherries.*—A large number of varieties of sweet cherry have been raised in the study of cross incompatibility, some of which are now under commercial trial.

Germany

Berlin; Institut für gärtnerischen Pflanzenbau, Friedrich-Wilhelms-Universität (director, Prof. Erich Maurer).—Breeding of tree fruits consists of the selection of vegetatively propagated rootstocks for apples, pears, sweet cherries, and plums. Around 3,000 clons are under observation.

Berlin; Institut für Obstbau, Friedrich-Wilhelms-Universität (director, Prof. Erwin Kemmer).—Investigations on the value of seedlings of varieties and from the wild stocks for stone fruits and pomes.

Geisenheim a.Rh.; Versuchs-und Forschungsanstalt für Wein-, Obst-, und Gartenbau (director, Prof. Dr. Rudloff).—Breeding of tree fruits has been conducted since 1884. A series of new apple and pear varieties has been developed through growing open-pollinated seedlings of named varieties or through hybridization of named varieties. Twelve varieties of pear and seven varieties of apple have been named.

Müncheberg (Mark); Kaiser Wilhelm-Institut für Züchtungsforschung (director, Prof. Dr. Rudorf).—An intensive program of investigation, particularly to develop disease-resistant varieties of fruits. In the apple work, the important objectives are to secure greater resistance to apple scab and to cold and frost, and to develop high-quality market and table varieties. In the work on scab resistance, mass infection of the seedlings of crosses between cultivated varieties and scab-resistant apples is practiced. Over 16,000 apple seedlings are under observation in this work.

(1) *Pears.*—The important objectives are to develop pears resistant to pear scab and to develop high-quality, large-sized summer pears. The testing of resistance to scab is similar to that of apples. Four thousand pear seedlings are under observation.

(2) *Cherries.*—One objective is to secure cherries resistant to brown rot. A large number of crosses of sweet × sour varieties have been tested. Tests of the cross- and self-sterility of the F_1 hybrids of sour × sweet cherries are also being made.

(3) *Plums.*—Testing of strong-growing seedlings of *Prunus cerasifera* from western Asia for their resistance to unfavorable climatic conditions, their adaptation, vigor, productiveness, and fruit quality. These are being crossed with other types of plums. Observations are made of a large number of seedlings of crosses between Mirabelle and Reine Claude types.

(4) *Apricots.*—Seedlings of the vigorous wild apricot of Asia are being tested for their resistance to climatic conditions, adaptation, vigor, productiveness, and fruiting value, and are being crossed with cultivated varieties.

(5) *Peaches.*—A large quantity of seedling material of varieties and crosses between varieties is being tested for the resistance of the buds against late frosts and winter temperatures and the resistance of the trees against peach leaf curl.

Zweigstelle, Naumburg (Saale); Biologische Reichsanstalt für Land- und Forstwirtschaft (director, Dr. Borner).—The objectives are the development of high-quality apple varieties and of stocks that are highly resistant to woolly aphis,

mildew, and scab. A large number of F_1 hybrids between resistant wild types and cultivated varieties are under observation.

Pillnitz a. d. Elbe; Staatliche Versuchs- und Forschungsanstalt für Gartenbau (director, Prof. Schindler).—Investigations on understocks for apples, pears, quinces, plums, cherries, and peaches. The objectives are to obtain good congeniality between stock and scion and to obtain cold resistance and good propagation qualities for the production of clon stocks.

Sweden

Alnarp; Lantbruks-, Mejeri-och Trädgårdsinstitut (director, L. Forsberg).—Investigations are conducted with apples, pears, plums, and cherries. Specially hardy apple varieties producing large yields are crossed with those of fine quality but not hardy in central and northern Sweden. A total of 3,750 seedlings, representing 136 combinations, are being grown. Crosses between triploid and diploid strains have yielded some trees that show promise. Crosses have been made between pear varieties for quality and productiveness, involving 41 combinations and 570 individual trees.

In plum and cherry breeding, difficulty has been experienced in obtaining satisfactory germination. Only one promising type of plum has been secured to date. A small number of crosses between soft-fleshed, high-yielding, early-bearing cherry varieties and the hard-fleshed, sweet varieties have been made.

Union of Soviet Socialist Republics

During the past decade plant explorers from the Soviet Union gathered a central breeding stations in that country much of the available material of the world that may be of promise for production there or for breeding purposes. Under the direction of the Institute of Plant Industry, 14 plant-breeding centers have been set up in different parts of the Union. At these centers, fruit breeding to develop varieties adapted to the different parts of the Union constitutes a major line of investigation. Genetic and cytological studies are being made.

Table 1.—*Origin of important apple varieties*

Variety	Where originated	How originated	When originated
Arkansas (Mammoth Black Twig).	Rheas Mill, Ark.	Chance seedling.	1833.
Arkansas Black	Benton County, Ark	do.	About 1870.
Baldwin	Lowell, Mass	do.	About 1740; widely introduced, 1784.
Ben Davis	Tennessee, Kentucky, or Virginia.		Shortly after 1800.
Black Ben	Washington County, Ark		About 1880.
Bonum	Davidson County, N. C.	Chance seedling.	Cataloged 1860.
Collins	Fayetteville, Ark.	do.	About 1865.
Cortland	New York Agricultural Experiment Station, Geneva.	Ben Davis × McIntosh.	Introduced 1912.
Delicious	Peru, Iowa	Chance seedling	Tree grew about 1880.
Esopus Spitzenburg	Esopus, N. Y.		Probably before 1800.
Fameuse	France or Canada		Distributed by earliest French missionaries before 1700.
Gano	Kentucky or Missouri		About 1875.
Golden Delicious	Porter, W. Va.	Chance seedling	Introduced 1916.
Gravenstein	Europe, probably Germany		Introduced to United States prior to 1826.
Grimes Golden	West Virginia	Chance seedling	Known in 1804.
Haralson	Minnesota Fruit Breeding Station, St. Paul.	Seedling of Malinda	Introduced 1922.
Hubbardston	Hubbardston, Mass	Chance seedling	Known in 1832.
Ingram	Springfield, Mo	Seedling of Ralls	Between 1844 and 1855.
Jonathan	Ulster County, N. Y.	Believed seedling of Esopus.	Described in 1826.
King David	Washington County, Ark.	Chance seedling	Introduced 1901.
Limbertwig	Knox County, Ohio (?)	Seedling	Soon after 1812.
McIntosh	Dundas District, Ontario, Canada.	Chance seedling	Propagated about 1870.
Maiden Blush	First known at Burlington, N. J.		Popular before 1817.
Missouri Pippin	Kingsville, Mo	Chance seedling	Seed planted about 1840.
Northern Spy	East Bloomfield, N. Y.	do.	Planted about 1800.

TABLE 1.—*Origin of important apple varieties*—Continued

Variety	Where originated	How originated	When originated
Northwestern Greening.	Waupaca County, Wis	Chance seedling	Introduced 1872.
Oldenburg (Duchess)	Russia		Imported to United States via England about 1835.
Ortley	New Jersey	Chance seedling	Described in 1817.
Paragon	Fayetteville, Tenn	do	From seed planted about 1830.
Payne	Everton, Mo	do	From seed planted about 1840.
Red Astrachan	Sweden		Imported into United States in 1835.
Red June	North Carolina	Chance seedling	Described as early as 1848.
Rhode Island Greening.	Probably near Newport, R. I.	do	Probably about 1700.
Rome Beauty	Lawrence County, Ohio	do	Introduced 1848.
Roxbury	Probably Roxbury, Mass	do	Prior to 1649.
Smokehouse	Lancaster County, Pa	do	Before 1800.
Stark	Probably Ohio	do	Described 1867.
Starr	Woodbury, N. J.	do	Propagated in 1865.
Stayman Winesap	Leavenworth, Kans	Seedling of Winesap	First fruited in 1875.
Summer Rambo	Europe, probably France	Unknown	Known in United States since 1817.
Tolman Sweet	Probably Dorchester, Mass	Chance seedling	Described in 1822.
Tompkins King (King).	Probably near Washington, N. J.	do	Before 1804.
Twenty Ounce	Unknown; possibly Connecticut.	do	Described in 1844.
Wagener	Penn Yan, N. Y	Seedling	Seed planted in 1791.
Wealthy	Produced by Peter Gideon, Excelsior, Minn.	Seedling of Cherry crab	Described in 1869.
White Pearmain	Unknown; first grown in Indiana.	Unknown	Cataloged in 1858.
Williams	Roxbury, Mass	Chance seedling	About 1750 or before
Willowtwig	Unknown; first grown in Ohio.	Unknown	Described in 1848.
Winesap	Unknown; grown very early in New Jersey.	do	Described 1817; known long before.
Winter Banana	Adamsboro, Ind	Seedling	About 1876.
Wolf River	Wolf River, Wis	do	Introduced 1881.
Yellow Bellflower	Crosswicks, N. J	do	Described in 1817.
Yellow Newtown	Newtown, N. Y	do	Well known as an old tree by 1759.
Yellow Transparent	Russia	Unknown	Imported by U. S. Department of Agriculture, 1870.
York Imperial	York, Pa	Seedling	Propagated about 1830; described 1853.

TABLE 2.—*Apple varieties developed in breeding work at agricultural experiment stations in the United States*

Place of origin and variety	Parentage [1]	Date crossed or seed collected	Date introduced	Characteristics
Iowa Agricultural Experiment Station, Ames:				
Adel	Mixed late	1902	1921	Hardy; Gravenstein type.
Afton	Wolf River × Harrington	1908	1921	Red; midwinter.
Ames	Allen Choice × Perry Russet.	1908	1921	Red; late keeper.
Earlham	Colorado Orange × Allen Choice.	1908	1921	Yellow Newtown type; hardy, late keeper.
Edgewood	Salome × Jonathan	1906	1921	Jonathan type; later keeper; free of Jonathan spot.
Harrington	(?)	1887	1914	Red; midwinter; good.
Hawkeye Greening	Vermont seedling	1900	1921	Large, productive, hardy, culinary fruit.

[1] Parents marked with (?) are somewhat uncertain.

Table 2.—*Apple varieties developed in breeding work at agricultural experiment stations in the United States*—Continued

Place of origin and variety	Parentage	Date crossed or seed collected	Date introduced	Characteristics
Iowa Agricultural Experiment Station, Ames—Continued.				
Joan	Anisim × Jonathan	1906	1932	Large, full red, very productive; November to February.
Macy	Northwestern Greening × Wealthy.	1908	1921	Wealthy type, larger; September.
Maud	McIntosh × Longfield	1906	1922	Red; August-September.
Monona	Wolf River × Harrington	1908	1921	Red, large, perfumed flavor; November-December.
Secor	Salome × Jonathan	1906	1921	Late keeper, best quality.
Sharon	McIntosh × Longfield	1906	1921	Hardy, very good quality; November-March.
Minnesota Agricultural Experiment Station, St. Paul:				
Minnehaha	Malinda, open-pollinated	1907	1920	Hardy, productive.
Folwell	Open-pollinated seedling of Malinda seedling.	1906	1922	Hardy; fruit of good size and quality.
Wedge	Ben Davis, open-pollinated	1908	1922	Vigorous, hardy tree; fruit good size and color; good baking apple.
Haralson	Malinda, open-pollinated	1907	1923	Tree very hardy, productive; fruit attractive; good storage quality.
Beacon	do	1907	1936	Very hardy; fruit early, attractive.
Missouri State Fruit Experiment Station, Mountain Grove:				
Faurot	Ben Davis × Jonathan	1901	1935	Tree resistant to disease; fruit medium size, high color, good storage and dessert quality.
Conard	do	1901	1935	Tree vigorous, disease-resistant; fruit large, colors well; good quality, tart; matures 1 week after Jonathan.
Wright	do	1901	1935	Fruit larger than Jonathan, attractive, colors well; dessert and storage quality good; tree vigorous, productive, very resistant to disease; fruit ripens with Jonathan.
Fyan	do	1901	1935	Tree spreading, vigorous grower, regular producer; fruit large, well colored, attractive; excellent storage quality; fruit ripens 2 weeks after Jonathan.
Grove	Ingram × Delicious	1915	1935	Tree fairly vigorous, spreading, late blossoming, resistant to scab, blotch, and blight; fruit attractive, good size, good quality, colors well; ripening season later than Winesap; excellent keeper.
Whetstone	Conard × Delicious	1915	1935	Tree vigorous, good producer; fruit smooth, large, colors well, uniform in size and shape; excellent storage quality, fair dessert quality.
Missouri Agricultural Experiment Station, Columbia:				
Whitten	Ingram × Delicious	1905	1925	Tree vigorous, prolific; fruit above medium size; yellow with red blush; quality good.
New York Agricultural Experiment Station, Geneva:				
Carlton	Montgomery × Red Astrachan.	1911	1923	Tree vigorous; fruit large, attractive, dark red; flesh white, tender, juicy, sprightly; ripens about with Wealthy.
Cortland	Ben Davis × McIntosh	1898	1915	Tree large, vigorous, spreading, hardy, productive; fruit slightly oblate, large, well colored, quality good; ripens almost with McIntosh but has better storage quality.
Early McIntosh	Yellow Transparent × McIntosh.	1909	1923	Tree vigorous, hardy, productive; fruit red, oblate, attractive; flavor good; season 10 days after Yellow Transparent.

TABLE 2.—*Apple varieties developed in breeding work at agricultural experiment stations in the United States*—Continued

Place of origin and variety	Parentage	Date crossed or seed collected	Date introduced	Characteristics
New York Agricultural Experiment Station, Geneva—Contd.				
Kendall	Zusoff × McIntosh	1912	1932	Tree moderately vigorous, apparently hardy; fruit large, well colored dark red; quality very good; season with McIntosh; possibly better storage quality.
Lodi	Montgomery × Yellow Transparent.	1911	1924	Tree of Yellow Transparent type, vigorous; fruit similar to Yellow Transparent but larger; ripens later.
Macoun	McIntosh × Jersey Black	1909	1923	Tree upright, moderately vigorous; fruit medium size, oblate, dark red, quality very good; season 1 month after McIntosh.
Medina	Deacon Jones × Delicious	1911	1923	Fruit of Delicious type and general quality but more highly colored; slightly later in season.
Milton	Yellow Transparent × McIntosh.	1909	1923	Tree hardy, vigorous; fruit pinkish-red, attractive, crisp, sometimes irregular in shape; quality good; season with Wealthy.
Newfane	Deacon Jones × Delicious.	1911	1928	Fruit of general Delicious type; quality good; in season with Delicious
Ogden	Zusoff × McIntosh	1912	1928	Tree hardy, productive; fruit large, oblate, dark red; quality good; ripens just before McIntosh.
Orleans	Deacon Jones × Delicious	1911	1924	Delicious type; in season with Delicious; keeps longer in common storage.
Red Sauce	Deacon Jones × Wealthy	1910	1926	Large, roundish-conic apple, red, with red flesh to core lines; ripens medium to late.
Sweet Delicious	Deacon Jones × Delicious	1911	1923	Fruits flatter than Delicious; large, sweet, aromatic
Sweet McIntosh	Lawver × McIntosh	1909	1923	Resembles McIntosh in appearance, flavor, and aroma; primarily adapted for home use.
Tioga	Sutton × Northern Spy	1899	1915	Tree large and vigorous, hardy, healthy; fruit large, round-oblate, late, yellow, tart; excellent culinary fruit.
Ohio Agricultural Experiment Station, Wooster:				
Franklin	McIntosh × Delicious	1925	1937	Fruit medium-sized; quality very good; yellow undercolor with bright, attractive red; season with Jonathan.
Downing	Gallia × Kirtland	1929	1937	Fruit above medium to large; very highly colored; quality good; blooming season late; storage to midwinter.
Kirtland	Ingram, open-pollinated	1915	1937	Fruit large, roundish oblate to oblong, attractive, well-colored; quality good; holds in storage till late winter; late blooming.
Warder	Rome, open-pollinated	1915	1937	Fruit medium-sized, roundish oblate, attractive and well colored; storage to end of January; late blooming.
Shaw	Ralls × Mother	1915	1937	Fruit above medium size, roundish oblong; quality good to very good; storage to late winter; late blooming.
South Dakota Agricultural Experiment Station, Brookings:				
Hibkee	Graft hybrid of Hibernal and Milwaukee.		1916	Flesh and core Milwaukee type, surface coloring of Hibernal.
Sereda	Harry Kaump × (Oldenburg?).		1916	Resembles Yellow Transparent in quality and season; yellow; juicy; sprightly.

Table 2.—*Apple varieties developed in breeding work at agricultural experiment stations in the United States*—Continued

Place of origin and variety	Parentage	Date crossed or seed collected	Date introduced	Characteristics
South Dakota Agricultural Experiment Station, Brookings—Continued.				
Caramel	Unknown		1919	Fruit medium size, yellow with red stripes. Fameuse type; sweet; winter apple of high quality. Complete hardiness for far north questionable.
Chance	do		1919	Fruit medium size, oblate, regular, red striped; flesh white; pleasant, subacid; season midwinter.
Sasha	Hibernal × Gravenstein		1919	Fruit medium size, yellow, oblate; sweet, excellent quality; subject to blight.
Chinook	Baldwin × Wild Crab from Minnesota.		1919	Fruit small, oblate, dark red; subacid; season throughout winter; hardy.
Anoka	Mercer × (Oldenburg?)		1920	Fruit medium size, round, striped; flesh white; subacid; season fall; tree very hardy, productive.
Maga	McIntosh × (Virginia Crab?).		1922	Fruit small, flattened, bright-red stripes; quality good; season late.
Goldo	Grimes Golden × (Oldenburg?).		1922	Fruit similar to Grimes Golden in appearance; quality good; tree hardy, vigorous.
Oxbo	Roxbury × (Oldenburg?)		1922	Fruit medium size, juicy, subacid; season late fall.
Bismer	Bismarck × Mercer		1927	Fruit roundish oblate, small, yellow striped with brown-red; flesh yellow; pleasant, subacid to sweet; early bearer; season probably winter.
Elta	Wealthy × (Hibernal?)		1927	Fruit medium to rather small, round-conical; rich orange-yellow, red striped; quality good, sweet; season late fall.
Wakpala	Mercer × Tolman Sweet		1928	Fruit rather small, round, yellow striped with red; flesh white; subacid, spicy, fragrant; late winter.
Tolmo	Tolman Sweet × Oldenburg?).		1932	Fruit medium size, color similar to Oldenburg; flesh white; pleasant, subacid; quality good; season fall.
Volga	Anisim × (Virginia Crab?)		1933	Fruit medium to below, round, conical, bright red; flesh red, fine; juicy, subacid; season late fall.
Lina	Seedling of Malinda		1933	Fruit conical, blushed; mild subacid; culinary fruit.
Kazan	Seedling of Anisim		1934	Fruit round, conical, brilliant red; flesh white; juicy, subacid; flesh red next to skin; fruit rather small.

Table 3.—*Apple crosses of which five trees or more have fruited, and number of promising seedlings resulting, in breeding work at State experiment stations in the United States*

Cross	Locality	Total fruited	Selections retained
		Number	*Number*
Adersleber Calville × Winter Banana	Geneva, N. Y	7	0
Adersleber Calville × Yellow Newtown	do	11	0
Allen Choice × Clemons No. 1	Iowa	41	0
Allen Choice × Perry Russet	do	5	2
Anisim, selfed	do	48	2
Anisim × Gano	do	30	0
Anisim × Jonathan	do	59	1
Anisim × King David	do	12	0
Anisim × Malinda	do	48	3
Anisim × Salome	do	8	0

Table 3.—*Apple crosses of which five trees or more have fruited, and number of promising seedlings resulting, in breeding work at State experiment stations in the United States*—Continued

PROGRESS IN PEAR IMPROVEMENT[1]

J. R. MAGNESS, Principal Pomologist,
Division of Fruit and Vegetable Crops
and Diseases, Bureau of Plant Industry

THE pear, like the apple, first came to us from western Asia by way of European countries. Its history in Europe closely parallels that of the apple. Apparently indigenous in the region from the Caspian Sea westward into Europe, whence so many of our fruits came, the pear was doubtless used as food long before agriculture was developed as an industry. Hedrick, in the Pears of New York, gives an excellent summary of its history and development during the last 3,000 years.

Nearly 1,000 years before the Christian Era, Homer listed pears as one of the fruits in the garden of Alcinous, thus indicating that they were known to the Greeks of his day. Prior to the Christian Era at least a few varieties were known. Theophrastus (370–286 B. C.) mentioned both wild pears and cultivated named varieties and described grafting. Pliny, of ancient Rome, named more than 40 varieties. With the migrations of the Romans the pear was distributed throughout temperate Europe.

At the time of the discovery of North America, a number of varieties were known in Italy, France, Germany, and England, but there was little progress in the culture of the pear, at least as far as is known, from the early Christian Era until about the beginning of the sixteenth century.

During the eighteenth and nineteenth centuries, there was a tremendous interest in pear breeding and improvement, particularly in Belgium and France. Hardenpont (1705–74), a priest in Mons, Belgium, sowed large quantities of pear seeds and introduced a dozen varieties having soft, melting, buttery flesh. Prior to his time only types with crisp, breaking flesh were known. Whether or not he did any hybridizing is not known. Van Mons (1765–1842), a physician and pharmacist at Louvain, Belgium, developed pear breeding on a large scale. At one time 80,000 seedlings were growing in his gardens. He originated or distributed over 400 varieties, 40 of which have proved of lasting merit.

Many other Belgian and French pear breeders were working on a smaller scale and introduced varieties of great value. The nineteenth century may well be considered the golden era of pear breeding in these countries. Most of the breeding consisted in planting seed of open-pollinated varieties and in selecting the superior types.

[1] This report is made possible only through the cooperation of staff members of the State agricultural experiment stations conducting pear-breeding investigations. Reports for their respective stations were submitted by W. H. Chandler and W. P. Tufts, of California; H. P. Stuckey, of Georgia; A. L. Schrader, of Maryland; A. N. Wilcox, of Minnesota; G. H. Howe, of New York; and F. C. Reimer, of Oregon.

The pear in Europe today, derived from *Pyrus communis* L., takes its place beside the apple in total production, in diversity of varieties, and in popularity. It is far more popular in Europe than in the United States.

THE PEAR IN NORTH AMERICA

THE early history of pear growing in North America parallels that of apple growing. Pear seed was brought to this country by the early settlers and possibly trees of some varieties. Pear trees were a part of the early colonial orchards. The Prince Nursery catalog listed 42 varieties in 1771.

About that time, however, fire blight or pear blight, the scourge that has frustrated the development of the pear industry in the United States ever since, became epidemic. William Denning, describing the disease in 1794, says he first saw it in 1780 in orchards of the Hudson Valley. How much earlier it might have occurred we do not know, neither are we sure where it came from. It seems most probable that it was present in some native host and became epidemic only when considerable orchard development occurred. Not for another century was the cause of the disease known. In 1882, Burrill, at the University of Illinois, discovered the cause of fire blight to be a bacterium working in the bark tissues.

The disease, which attacks roots, crown, trunk, limbs, blossoms, fruit, and leaves, proved such a menace that pear growing with varieties from Europe, or with seedlings produced from them, never developed to a major industry in the eastern United States. Only in a few sections having relatively cool summers and mild winters has the culture of the European type of pear been successful in the Eastern States. Such conditions are found in relatively narrow strips on the south and east sides of Lake Michigan, Lake Erie, and Lake Ontario. Elsewhere the warm, humid summers have been so

---

ALL *of the known species of pears are native to Europe, Asia, and northern Africa. There are no native American species, and none are known in the Southern Hemisphere. Within these species and varieties, however, we have all the characters needed to produce pears suitable for this continent—fruit of high quality, winter-hardy, and above all resistant to fire blight, the scourge that has made the growing of superior pears impossible throughout much of the United States and difficult even in favored regions. To combine these characters properly constitutes a great challenge to the American plant breeder. He has made a small but promising start, and if, with the raw materials available, the problem is not solved within the next century, it will indeed be a reflection on his scientific ability and energy.*

favorable for fire blight that the development of commercial orchards with these types of pears has not been very successful (fig. 1).

An event of great importance from the standpoint of eastern pear growing was the introduction of the Chinese or sand pear into the United States. The sand pear (*Pyrus serotina* Rehd.) was growing in the United States by 1840, apparently having come in by way of Europe. These pears are relatively resistant to blight. They are coarse-fleshed, generally contain many grit cells, and are themselves of very inferior quality. Because of their blight resistance, however, they were rather widely disseminated over the eastern United States.

Figure 1.—Pear orchard destroyed by fire blight.

Soon hybrids between the sand pear and *P. communis* varieties began to appear. The Le Conte, Kieffer, Garber, Douglas, and more recently the Pineapple, are the most important of these hybrids. All of these are very inferior in quality as compared to the "buttery" pears of Europe. They are sufficiently resistant to blight, however, to permit growing in most parts of the eastern United States. They are widely planted in home orchards and in small commercial orchards at the present time.

Another event of importance was the importation of a large number of varieties from northern Russia. Since 1879, when the first shipment was made, 70 to 80 varieties have been brought in and tested in Iowa and other northern sections. These are hardy but generally poor in quality and very subject to blight. They are of value only for breeding for hardiness, and probably some of the oriental types that combine hardiness and blight resistance are superior for this purpose.

138904°—37——40

In the United States the greatest development of pear growing has centered in the moderately warm, dry valleys of the three Pacific Coast States. Pears were established in California long before that State became a part of the Union, having been introduced by the Mission Fathers with the earliest white settlements. In the valleys of the Pacific States, where there is little summer rainfall and the nights are relatively cool, fire blight is less rampant than in the eastern United States. Most of the European varieties reach a high degree of perfection in these areas. Although blight is a constant menace in many of the sections at the present time, methods have been developed so that it is possible to control it commercially, chiefly by means of careful surgery.

The principal pear varieties grown in the United States today are listed in the appendix, with notes on their origin.

It is apparent that, in contrast to apples, our highest quality pear varieties have mainly been imported directly from Europe. The most important—Bartlett, Anjou, Bosc, and Winter Nelis—are all direct European importations. Among our leading varieties, only those selected primarily because of blight resistance have originated in the United States. These include Seckel, a blight-resistant variety apparently of straight *Pyrus communis* origin, and the *P. communis* × *P. serotina* hybrids. European breeders have worked with pears to a far greater extent than with apples, and in all respects except resistance to fire blight their best varieties have so far proved superior to those that have developed as chance seedlings in the United States.

Objectives in Pear Breeding in the United States

One objective stands out above all others in the breeding of pears in the United States. This is to secure resistance to fire blight, combined with satisfactory dessert quality. In few regions east of the Rocky Mountains can varieties be grown successfully unless they have a fairly high degree of blight resistance. Varieties available at the present time that have fair blight resistance—primarily *Pyrus communis* × *P. serotina* hybrids—are all of inferior quality as compared to the better *P. communis* varieties. The securing of blight resistance coupled with quality is important in every section of the United States and is the predominent need in at least three-fourths of the potential pear-growing territory of the country.

A second and more localized objective is the securing of additional hardiness in pear varieties for growing in the northern Great Plains and other areas that have very cold winters. Varieties of *Pyrus communis* having good dessert quality do not possess sufficient hardiness to thrive in those regions.

Blight-resistant varieties are needed that also have high dessert and culinary quality and that ripen at intervals from early summer until late fall. Late-ripening varieties with good storage quality are especially needed. At the present time no varieties are available that have these characteristics and are adapted for growing east of the Rocky Mountains. Varieties of European origin meeting these qualifications are grown successfully in the Western States, but even there the problem of blight control is of tremendous importance and involves a heavy expense to growers.

Rootstocks are also needed that combine blight resistance with satisfactory hardiness, congeniality to scions, and adaptation to environment. Fire blight frequently attacks the roots as well as the tops of the trees, and rootstocks that are blight-resistant are a primary need in most regions of the United States where pear growing is attempted.

Material Available for Pear Breeding in the United States

The cultivated pear varieties of Europe, derived from *Pyrus communis*, generally produce fruit of high quality. Superior varieties produced by European breeders have the buttery texture, relative freedom from grit cells, and aromatic to spicy flavors needed in pears of high quality. While these varieties vary considerably in blight resistance, none of the high-quality European sorts are known to be sufficiently resistant to thrive in the regions where blight is most serious.

The snow pear, *Pyrus nivalis* Jacq., native to southern Europe and cultivated there for making perry, the fermented pear juice popular as a beverage in Europe, is not cultivated in the United States. Trees of this species are very susceptible to blight, and it appears to have little merit as breeding material except possibly for developing perry types if a perry industry should be built up in this country.

The sand pear, *Pyrus serotina*, is native to central and eastern China and is cultivated in China and Japan. The fruit is heavily russeted and commonly apple-shaped, and the flesh is very gritty. Trees of this species are variable in resistance to fire blight but on the average much more resistant than *P. communis*. It hybridizes freely with *P. communis* varieties, and several of the hybrids are important American varieties because of their blight resistance, although all are lacking in quality.

The Ussurian pear, *Pyrus ussuriensis* Maxim., is native to northern China and eastern Siberia. This is the hardiest of pears. The tree is a rather slow grower but very resistant to blight. It is cultivated, and a number of varieties are known in its native habitat. The best of these varieties are soft-fleshed, not excessively gritty, juicy, and subacid to acid in flavor. The trees bloom very early. This appears to be an extremely valuable species for breeding to obtain blight resistance and hardiness.

The Callery pear, *Pyrus calleryana* Decne., is native to central China. The trees are medium to large, vigorous, and bloom early. The fruit is small and seems valueless. The trees are very blight-resistant and may be valuable as stocks for regions having mild winters. They are of questionable hardiness for the colder sections.

The birchleaf pear, *Pyrus betulaefolia* Bunge, is native to central and northern China. The tree is large and vigorous. It blossoms late and produces small, valueless fruit. Many trees of this species are quite susceptible to blight, but there are some resistant types. This species propagates readily from root cuttings, so the blight-resistant types are of possible value for rootstock purposes.

Although there are several other species—a total of 20 to 25 according to the usual botanical classifications—the 6 listed above seem to be of greatest economic importance. All of these species will, so far as known, hybridize readily among themselves.

It is of interest to note that all of the known species of pears are native in Europe, Asia, and northern Africa. There are no native American species; neither are any known in the Southern Hemisphere. Within these species and their varieties we have all of the characters—high-quality fruit, blight resistance, and hardiness—needed to produce pear varieties suitable for North American conditions. To combine these characters in varieties adapted to the different regions of the United States constitutes a great challenge to the American plant breeder. Only a small start has been made on this problem. With the raw materials available, however, if American plant breeders do not solve this problem within the next century it will indeed be a reflection on their scientific ability and energy.

Figure 2.—Blossoming spurs of pear, in proper stage of development for emasculation

Pear-Breeding Work Now in Progress in the United States

The technique of collecting pollen, emasculating blossoms (fig. 2), and cross-pollinating in pears is in all respects similar to that already outlined for apples.

Pear breeding at the California Agricultural Experiment Station was started in 1928. The objective is to obtain superior *Pyrus communis* varieties ripening at intervals throughout the season, including some with good storage quality for holding through the winter months. Approximately 1,700 open-pollinated seedlings of the leading *P. communis* varieties are being grown. In 1931, crosses to give approximately 3,000 seedlings were made. These consisted of Bartlett crossed with Winter Nelis, Easter Beurré, Comice, Hardy, Anjou, P. Barry, and Bosc.

At the Georgia Experiment Station at Experiment, Ga., a considerable collection of varieties is maintained and studied for resistance to blight. Active breeding work is not under way. The variety Sowega, introduced in 1930 by J. J. Parish, Adel, Ga., is reported to be of high quality and very resistant to blight.

Pear-breeding work in Iowa was started by C. G. Patten shortly after 1867. The assistance Patten received from public institutions has been outlined briefly in connection with his work with apples. Patten's work was significant in demonstrating the possibility of developing pears sufficiently hardy to thrive in the upper Mississippi Valley. He grew a large number of open-pollinated seedlings of *Pyrus ussuriensis*. This oriental pear was growing adjacent to *P. communis* varieties, and many of the seedlings are obviously hybrids. The

seedling trees were more vigorous than the original *P. ussuriensis* and proved as "hardy as an oak." These hybrids have proved more hardy in tests during the last 20 years than pears from any other source. Twenty-five of Patten's seedling pears have been selected for further breeding work. One variety, the Patten, a cross of Orel 15 × Anjou, was introduced by the Iowa Agricultural Experiment Station in 1922. Crosses and backcrosses of Patten's seedlings with *P. communis* varieties were made between 1918 and 1928. Much of this work was lost when it was necessary to abandon the station in 1932.

Pear-breeding work at the University of Maryland, College Park, was begun in 1905. Hybrids consisted mainly of crosses of Kieffer with *Pyrus communis* varieties, particularly Seckel and Anjou, although a few crosses of *P. communis* × *P. communis* were made. A total of 1,411 seedlings from crosses made between 1905 and 1917 have been grown to fruiting. Only one, a Kieffer-Anjou hybrid, seems to have merit. A number of these hybrids are being maintained for further determination of their blight resistance.

In Michigan during the period between 1916 and 1919, W. F. Wight and Don Ward, of the United States Department of Agriculture, hybridized pears at the South Haven Horticultural Experiment Station at South Haven. These hybrids were grown to fruiting cooperatively by the Department and the South Haven station. The parents were for the most part moderately blight-resistant types of good quality. Of all the crosses made, Barseck × Bartlett has been most outstanding. A number of the progeny of this cross have produced pears of excellent quality, apparently with some blight resistance, the degree of which has not been satisfactorily determined. A number of these selections are under test in Michigan and at the United States Horticultural Station at Beltsville, Md.

A limited amount of breeding work was started at the Minnesota Agricultural Experiment Station in 1908. The primary objective has been to obtain hardiness and blight resistance. In that year, 300 seedlings of an unknown variety from Manchuria were planted. Two of these have been selected as of horticultural value. Since 1924, a considerable number of hybrids of *Pyrus communis* × *P. ussuriensis* have been made. These are grown in the field without any protection, and only the hardiest survive for planting in the trial orchards. Approximately 700 of these seedlings have survived the Minnesota winters and are being grown to fruiting.

Pear breeding at the New York (State) Agricultural Experiment Station at Geneva started in 1892. Relatively few seedlings were grown before 1906. By 1921, 1,775 seedlings had been grown, most of which have fruited. Approximately 5,000 seedlings have been set out since 1921, of which only a few have fruited as yet. The varieties used in crossing and the number of times they were used are as follows: Anjou, 31; Bosc, 59; Bartlett, 85; P. Barry, 11; Clairgeau, 16; Cayuga, 16; Dana Hovey, 12; Ewart, 10; Gorham, 13; Kieffer, 24; Lincoln Coreless, 12; Ovid, 9; Phelps, 35; Pulteney, 41; Seckel, 77; Sheldon, 20; Tyson, 28; Winter Nelis, 17; and Willard, 17. The New York work has consisted primarily in the hybridizing of *Pyrus communis* varieties to produce high-quality types. The objective has been to obtain pears equal to Bartlett in size, appearance, and quality, but ripening through

a long season. Recently, added emphasis has been placed on the testing of all seedlings for blight resistance. The varieties introduced as a result of the breeding work in New York State are listed in the appendix.

By far the most extensive project in the United States on the testing of known varieties and species of pears for their resistance to blight has been conducted at the Southern Oregon Branch Experiment Station, Talent, Oreg. (fig. 3). Tests have included practically all of the known species, as well as a number of the Asiatic varieties of *Pyrus serotina* and *P. ussuriensis*. Eighty-five *P. communis* varieties and hybrids have been inoculated repeatedly, while 500 pear varieties have been grown in orchard form where they were exposed to natural infection from great quantities of blight in the orchard. The earlier results of these experiments are recorded by Reimer (*7*).[2] This work gives much information on the relative blight resistance of various *Pyrus* species and varieties and indicates clearly the material of greatest value for breeding for blight resistance.

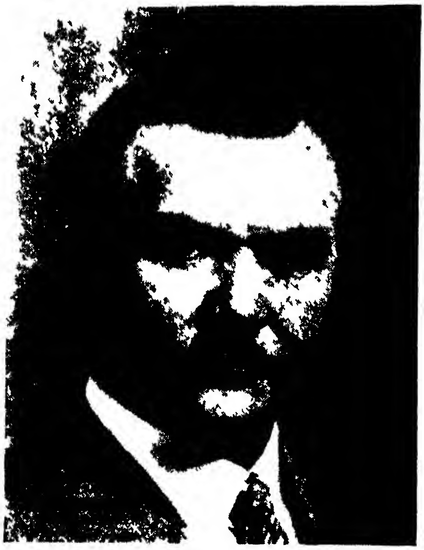

Figure 3.—F. C. Reimer, whose extensive work in determining the extent of blight resistance in practically all known species and varieties of pears serves as a foundation in breeding for blight resistance.

The present work has two objectives—(1) to develop dependable, hardy, congenial, blight-resistant rootstocks for pears; and (2) to develop high-quality, blight-resistant varieties. Ba Li Hsiang, a highly resistant *Pyrus ussuriensis* variety, pollinated with another resistant variety, gave seedlings sufficiently blight-resistant for rootstocks, but such seedlings have proved unsatisfactory for some of the commercial *P. communis* varieties and have been discarded. Seedlings of *P. calleryana* resulting from resistant trees planted so that both pollen and seed parents are resistant have proved highly resistant to blight and appear to be excellent rootstocks in southern Oregon. They may lack sufficient hardiness for the colder sections of the country. By mass selection methods, seedlings of *P. communis* have been found resistant to blight. From 10,000 seedlings, 10 proved highly resistant, and these 10, when pollinated with other resistant varieties, transmit a high degree of resistance. Three of these have produced seedlings 100-percent resistant to root blight when pollinated with another resistant type.

In breeding for resistant varieties of high quality, varieties of *Pyrus ussuriensis* crossed with Anjou, Bartlett, Bosc, and Comice have given only poor-quality varieties, and all have been discarded, though a part of the seedlings were blight-resistant.

---

[2] Italic numbers in parentheses refer to Selected References to Literature, p. 627.

In 1915, Reimer saw a small Anjou seedling on Benjamin Buckman's farm at Farmingdale, Ill., which was just coming into bearing, with fruit of good size and mediocre quality. The tree was free from blight while the disease was rampant in other varieties surrounding it. Scion wood was obtained and the tree propagated at the Southern Oregon Experiment Station. Extensive inoculation work at the station has proved that this tree is highly resistant to blight. Buckman named the tree Farmingdale in honor of his town.

During the last 5 years several thousand trees have been produced which are crosses between Farmingdale and Anjou, Bartlett, Bosc, Comice, and Seckel. Approximately 75 percent of these seedlings have blighted when inoculated. The remainder have so far proved highly resistant even when repeatedly inoculated. The oldest of these crosses should come into bearing during the next year or two. It is hoped that among these resistant trees at least a small number will possess the good quality of the fine-flavored varieties used as one parent in each cross and the blight resistance of the Farmingdale.

Figure 4.—Merton B. Waite, whose experiments in the United States Department of Agriculture showing the necessity for cross-pollination in horticultural varieties of pears led the way to the great amount of research conducted since, not alone with pears but with all orchard fruits. He was also an early leader in breeding pears for blight resistance.

With one exception, all the crosses have proved vigorous. This one exception is Anjou × Farmingdale, these seedlings being only moderately vigorous. Furthermore, the leaves of 20 percent of the seedlings resulting from this cross possessed a waxy white color (devoid of chlorophyll), and the seedlings died when they were from 2 to 4 inches high. This is probably the result of inbreeding, since Farmingdale itself is a seedling of Anjou.

Breeding work to obtain pear varieties resistant to blight was started at the Tennessee Agricultural Experiment Station in 1925, though a limited amount of hybridizing had been carried on earlier. The work since 1925 has consisted of crossing resistant species such as *Pyrus serotina*, *P. ussuriensis*, and *P. calleryana* with the more resistant varieties of *P. communis*. Approximately 3,000 seedlings from these crosses are now being grown, and additional hybridization is under way.

In the United States Department of Agriculture breeding investigations to develop pear varieties resistant to fire blight were started

by M. B. Waite at the Arlington Experiment Farm, Arlington, Va., about 1908 (fig. 4). The early work consisted of crossing Kieffer with Seckel, Anjou, and Bartlett. Several thousand seedlings from these crosses have been grown to fruiting. Several selections made from these earlier seedlings combine good fruit quality with blight resistance. At least one selection seems to be very blight-resistant and has good fruit characters from the standpoint of flesh texture,

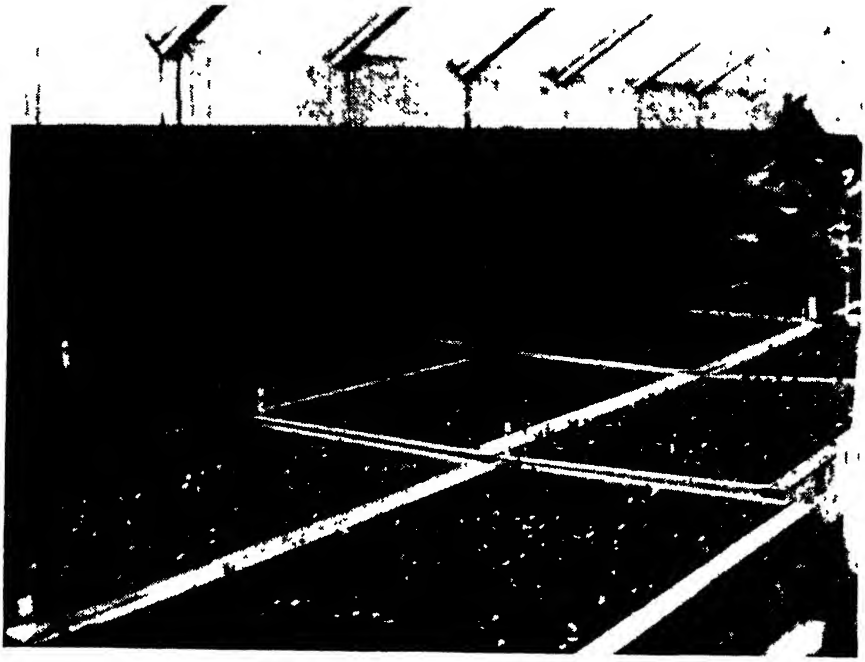

Figure 5.—Hybrid pear seedlings growing in the greenhouse.

size, and quality. None of the selections has been named, but they are worthy of general testing. At the present time, around 5,000 seedlings from the above crosses are being grown to fruiting (fig. 5). These are inoculated with blight each year in addition to being exposed to field infection. Resistance to blight, resistance to leaf spot, and fruit characters are being recorded.

A few crosses between high-quality *Pyrus communis* varieties have been made at Palo Alto, Calif., by W. F. Wight, of the United States Department of Agriculture. The purpose in these crosses is to obtain pears of high dessert quality, ripening at intervals through the summer, and also varieties suitable for winter storage.

A list of pear material of special value for breeding purposes, with the institutions at which it is maintained, is given in the appendix. Some of the results of hybridization are illustrated in figure 6.

For a discussion of pear-breeding work under way in other countries, see pages 602–604.

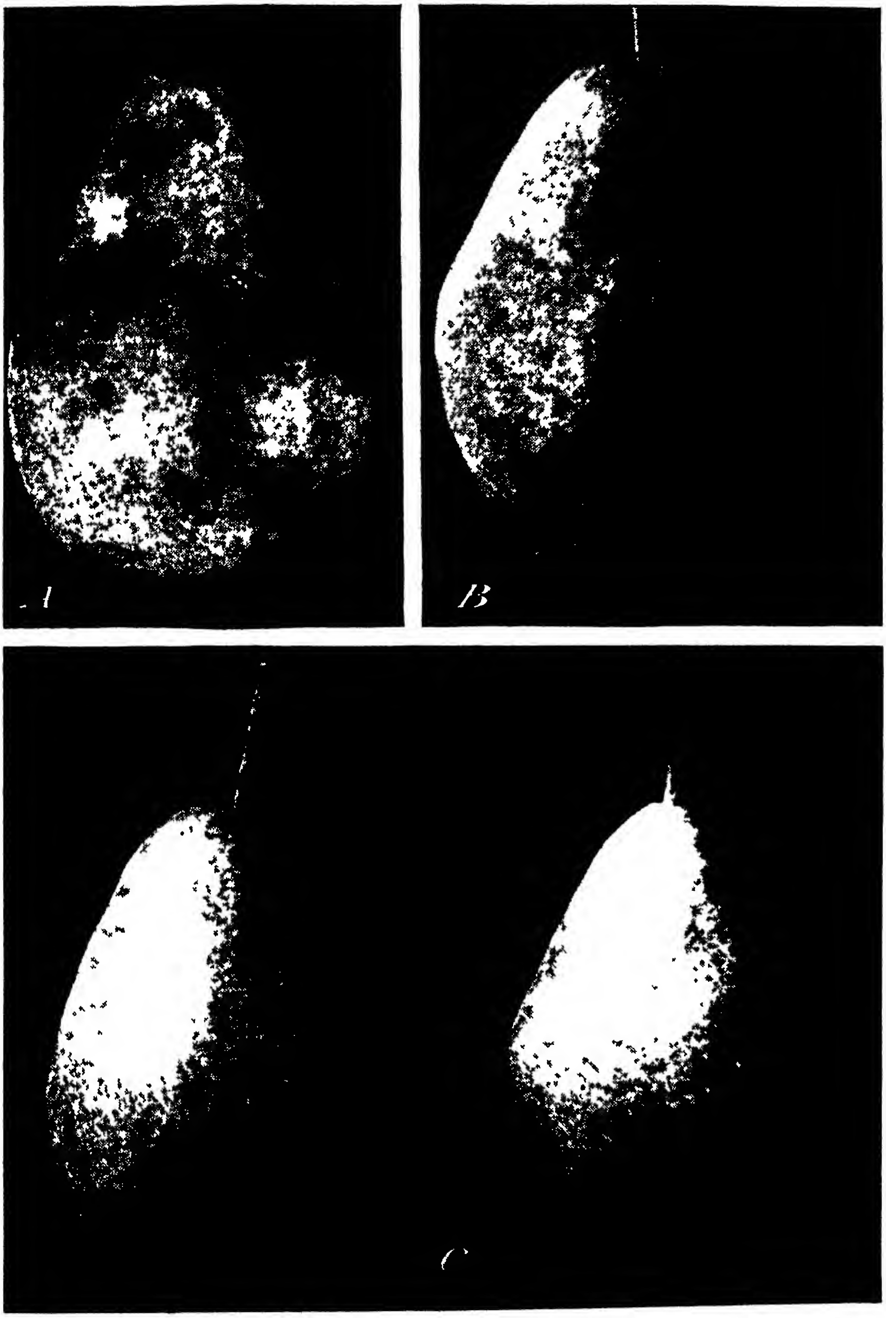

Figure 6.—The fruits of hybridization: *A*, Bartlett pear (*Pyrus communis*); *B*, Kieffer a hybrid of *P. serotina* × *P. communis*; *C*, hybrid variety from a cross of Kieffer × Bartlett.

CYTOLOGY AND GENETICS OF THE PEAR[3]

THE basic chromosome number in the germ cells of pear species is 17, the same as that of the apple. Among European varieties, approximately one-fourth to one-third of those examined to date are triploids, this ratio being about the same as for apples in the United States. These forms with 51 somatic chromosomes, like the triploid apples, generally produce only a small percentage of viable pollen. According to unpublished data from the New York (State) Agricultural Experiment Station, all of the pear varieties important in the United States are diploids with 34 chromosomes in the vegetative tissues. Most of these diploid varieties produce a relatively high percentage of viable pollen.

Recently two bud mutations that may be tetraploids have been found in pears, one in Bartlett, the other in Winter Nelis. These produce giant fruit similar in general appearance to the parent variety but coarser textured. In the case of the Bartlett at least, the fruit is inferior in quality to the parent variety. If cytological examination proves these to be true tetraploids, they may prove to be of much interest and value from the standpoint of breeding, as crosses of tetraploids with diploid varieties should produce triploids.

Few studies have been reported to indicate the type of inheritance that may be expected in pears. Since all varieties of *Pyrus communis* are highly heterogeneous, and since selfing in most varieties is impracticable because of failure of self-pollinated blossoms to produce viable seed, inheritance studies are difficult.

Size of fruit appears to be controlled by many factors. Seckel gives mainly small-sized fruits even when hybridized with large-fruited types, though many intermediate-sized fruits are found in the progeny, a few approaching the size of the larger parent.

The low quality of oriental pears seems to be dominant over high quality of other groups, though intermediate forms sometimes are found. No high-quality progeny has occurred in F_1 hybrids of *Pyrus serotina* × *P. communis* or *P. ussuriensis* × *P. communis*. In backcrosses of these F_1 hybrids with high-quality *P. communis* varieties, some good-quality types result. In 11 trees from Kieffer (*P. communis* × *P. serotina*) × Anjou, fruited in 1936 by the Bureau of Plant Industry, fruits of 2 rated good and 4 fair to good. In 132 Kieffer × Seckel hybrids, fruit of 17 rated as good and 24 as fair to good in quality.

Kieffer, a sand pear hybrid, probably carries russet as a recessive character. In the crosses with russeted Seckel, 23 hybrids were heavily russeted, 45 semirusseted, and 64 smooth. These results indicate that in this cross russet is recessive to smooth skin. Kikuchi has reported that within *Pyrus serotina*, russet behaves as a dominant. In 122 Kieffer (subacid) × Seckel (sweet) hybrids, 26 produced sweet fruit, like Seckel, 82 subacid fruit, and 14 acid fruit. These results would indicate that, as in apples, sweetness tends to be recessive but that the character is controlled by more than one gene.

No study has yet been reported on the transmission of blight resistance. Reimer finds wide variability in blight resistance of individual seedlings of most of the species studied, with occasional blight resistance appearing in all species studied. Crosses of highly

[3] This section is written primarily for students or others professionally interested in breeding or genetics.

resistant Farmingdale with blight-susceptible varieties have resulted in about 25 percent blight-resistant seedlings in the F_1 progenies.

APPENDIX

TABLE 1.—*Leading pear varieties of the United States*

Variety	Parent species	By whom, where, and how originated
Angouleme	*Pyrus communis*	Wild seedling, Angers, France. Propagated 1808, introduced into the United States before 1830.
Anjou	do	A seedling of Van Mons, according to Bunyard. An old French variety, according to Hedrick. Introduced into the United States 1842.
Bartlett	do	Raised by a Mr. Stair at Aldermaston, Berkshire, England, about 1770. Brought to the United States about 1797.
Bosc	do	A Van Mons variety, 1807. Introduced into the United States in 1832.
Clairgeau	do	Raised by Pierre Clairgeau, Nantes, France, about 1830. Introduced into the United States 1854.
Clapp Favorite	do	Thaddeus Clapp, Dorchester, Mass. Reported Massachusetts Horticultural Society, 1860.
Comice	do	Comice Horticole, Angers, France, 1849. Introduced into the United States in 1850.
Dana Hovey	do	Francis Dana, Roxbury, Mass. Introduced 1854.
Douglas	(*P. communis* × *serotina*) × *P. communis* Kieffer × Angouleme.	O. H. Ayer, Lawrence, Kans., about 1897.
Easter Buerré	*Pyrus communis*	Capucin Monastery, Louvain, Belgium, about 1823; the United States by 1837.
Flemish Beauty	do	Wild pear found by M. Chatillon, Alost, Belgium. Introduced by Van Mons 1818; into the United States about 1830.
Forelle	do	Germany about 1700, the United States 1823.
Garber	*Pyrus communis* × *serotina*.	J. B. Garber, Columbia, Pa., before 1880.
Glou Morceau	*Pyrus communis*	M. Hardenpout, Mons, Belgium, about 1750, the United States about 1820.
Hardy	do	M. Bonnet, Boulogne-sur-Merd., France, about 1820. Introduced into the United States before 1862.

TABLE 1.—*Leading pear varieties of the United States*—Continued

Variety	Parent species	By whom, where, and how originated
Howell	*Pyrus communis*	Thomas Howell, New Haven, Conn., from seed of Jonah planted about 1830.
Idaho	do	Seed planted by Mrs. Mulkey, Lewiston, Idaho, about 1867.
Kieffer	*Pyrus communis* × *serotina*. (Probably sand pear × Bartlett.)	Raised from sand pear seed by Peter Kieffer, Roxborough, Pa., about 1863.
Le Conte	*Pyrus communis* × *serotina*.	Originated in the United States before 1850. Exact history unknown.
P. Barry	*Pyrus communis*	Seedling of Belle Lucrative, raised by B. S. Fox, San Jose, Calif.; fruited 1873.
Pineapple	*Pyrus serotina* × *communis*.	Large seedling tree on plantation of Mrs. B. N. Stuckey, Nesmith, S. C.; possibly brought in from China or Japan.
Seckel	*Pyrus communis*	Chance seedling near Philadelphia about 1800.
Sheldon	do	Premises of Major Sheldon, Huron, N. Y., from seed planted about 1815.
Vermont Beauty	do	Seedling in nursery of B. Macomber, Grand Isle, Vt., about 1880. Hedrick says it is indistinguishable from Forelle.
Wilder Early	do	Chance seedling found by Charles A. Green in Chautauqua Co., N. Y., about 1884.
Winter Nelis	do	Raised from seed by Jean C. Nelis, Mechlin, Belgium, about 1800.

TABLE 2.—*Pear varieties introduced by the New York (State) Experiment Station*

Variety	Parentage	Year crossed	Date introduced	Value
Cayuga	Seckel, open-pollinated	1906	1920	Home and roadside markets.
Clyde	do	1908	1932	Home and local market.
Covert	Bartlett × Dorset	1912	1935	Commercial and export.
Early Seckel	Seckel, open-pollinated	1906	1935	Home and roadside markets.
Gorham	Bartlett × Malines	1910	1923	Commercial market.
Ovid	Bartlett × Dorset	1912	1931	Late winter pear.
Phelps	Winter Nelis × Russet Bartlett	1912	1925	Late home and market.
Pulteney	do	1912	1925	Fall home and market.
Willard	Bartlett × Dorsett	1912	1931	Late winter pear.

TABLE 3.—*Workers on pear breeding in the United States*

Institution	Location of work	Former workers	Present workers
California Agricultural Experiment Station.	Berkeley, Calif.; Davis, Calif.		W. H. Chandler, W. P. Tufts.

Lists of Pear Material of Special Value for Breeding Purposes

The following institutions have trees of practically all of the *Pyrus* species:
- Arnold Arboretum, Harvard University, Jamaica Plain, Mass.
- California Agricultural Experiment Station, Davis, Calif.
- Southern Oregon Branch Experiment Station, Talent, Oreg.

At the California Station the following varieties not generally available are growing:

Pyrus communis:
- Bollweiller,
- Bonnefond,
- Bordeaux,
- Burkett,
- Caisson,
- Crocker,
- Felix Sahuit,
- Guyot,
- Lady Clapp,
- Large Sugar,
- Longworth,
- Lowe Seedling,
- Marillat,
- Messire,
- Nantes,
- Remy Chatenay,
- Sageret,
- Souvenir de Cronstadt,
- Superfin,
- Thirriott.

P. sinensis:
- Pin Li (P. I. 38263),
- P. I. 40352,
- Nanshi (P. I. 30352).

At the Minnesota Agricultural Experiment Station, St. Paul, Minn., the following material has been tested for hardiness under field conditions, with the results indicated:

1. Completely winter-hardy, tested 10 to 15 years:
   - Minn. Nos. 3 and 4,
   - Minn. Nos. 5, 6, and 7 (seedlings of King Karl × sand pear),
   - Phiel,
   - Russian sand pear,
   - Saponsky.
2. Completely winter-hardy, tested 5 years:
   - Borgman,
   - Cepe Zum Mur (Russia),
   - Patten Nos. 5, 1204, 1205.
3. Completely winter-hardy during tests of 3 to 5 years:
   - Pushken,
   - *Pyrus communis* L., P. I. 47093 et al.,
   - *P. ussuriensis ovoidea* Rehd., P. I. 44051,
   - *P. ussuriensis* Maxim., P. I. 44235, 44237, 44275, et al.,
   - Scandinavian varieties (top-worked branches only):
     - Aldonspare,
     - Esperen Herripare,
     - Furstligt Tafelparon,
     - Grapare,
     - Grev. A. D. Moltke,
     - Johantorp,
     - Juli Dekan,
     - Lübecker Prinzessinpare,
     - Rostbergersmott.
4. Relatively winter-hardy during tests of 3 or more years:
   - *P. betulifolia* Bunge, P. I. 39547,
   - *P brestschneideri* Rehd.,
   - *P. communis* L., P. I. 33207 et al.,
   - *P. phaeocarpa* Rehd., P. I. 32741, 39541, 43185, 44276,
   - *Pyrus* sp., "Favorita," P. I. 33207,
   - *P. ussuriensis* Maxim., P. I. 47094, 55967, 55970,
   - Van Fleet hybrid, P. I. 43443.
5. Relatively hardy, but not completely hardy in Minnesota; tested 5 years or more:
   - Beierschmitt,
   - Chang,
   - Mendel,
   - Parker,
   - Patten Nos. 1200, 1206,
   - Simola,
   - Tait, Nos. 1, 2, and 4.

6. Other species, severely winter-injured but surviving:
   P. calleryana Decne., P. I. 47261,
   P. chinensis,
   P. phaeocarpa Rehd., P. I. 64229,
   Pyrus sp., "Surprise," P. I. 45901,
   Pyrus sp., P. I. 46566, 56012, 64223,
   Pyrus sp., Van Fleet hybrid, P. I. 55805,
   P. ussuriensis Maxim., P. I. 46587.

The New York (State) Agricultural Experiment Station, Geneva, N. Y., has the following pear varieties that are not generally available in the United States:[4]

Admiral Gervais, P. I. 91198,
Alexander Lambré, P. I. 91199,
Ba Li Hsaing,
Barronne de Mello,
Baudry,
Belle Guérandaise, P. I. 91200,
Beurré d'Arenberg (syn. of Glou Morceau),
Beurré Bedford,
Beurré Cadelien,
Beurré Dumont
Beurré Fouqueray,
Beurré Six (P. I. 91201),
Ewart,
Favorita,
Fondante Thirriot,
Gdula,
Hessle,
Lung Li, P. I. 46587,
Koestliche von Charmeau,
Kontoula, P. I. 47227,
Laxton,
Laxton Superb,
Louis Pasteur,
Marie Benoist,
Michurin's,
Ming,
Ne Plus Meuris,
Noveau Poiteau, P. I. 91207,
Nouvelle Fulvie,
Packham Triumph,
Passe Crassane,
Pastoren Birne (syn. of Vicar of Winkfield),
Petite Marguerite, P. I. 91208,
Petre,
President Barabé, P. I. 91209,
Satisfaction,
Soldat Laboureur, P. I. 91210,
Tang Li,
Triomphe de Vienne,
Vergules,
Miscellaneous *Pyrus* species.

At the Southern Oregon Branch Experiment Station, Talent, Oreg., 500 varieties of pears have been collected. Some of these have died of blight and are no longer available. These are listed in Oregon Station Bulletin 214.

[4] Names are substantially as submitted by the station Some are not in full accord with the code of nomenclature.

GRAPE DEVELOPMENT AND IMPROVEMENT

ELMER SNYDER, Pomologist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry [1]

THE present commercial grape industry in the United States has developed along two main lines. On the Pacific coast the industry has depended upon the importation and improvement of varieties of the grape of the Old World, *Vitis vinifera* L., while in the remainder of the country the industry has been based upon the development of the American species indigenous to the region, hybrids of these species, and finally hybrids of native species with *V. vinifera*. On the other hand, the industry in the Old World originated actively from the single species *V. vinifera*. This species has also played a vital part in the improvement of our native grapes. It was known in prehistoric times. Sacred writings and ancient myths and fables extol the value of this grape. Seeds of the grape have been found in the remains of lake dwellings of the Bronze Age in Switzerland and Italy and in the tombs of ancient Egypt. Remains of grape leaves have also been found in calcareous rocks in France, where they were apparently deposited in prehistoric times. It is the belief of botanists that the ancient home of this species was the Caspian Sea region.

DISTRIBUTION AND EARLY HISTORY

FROM its original habitat the grape was carried westward into favorable locations in Africa and Europe and eastward in Asia. The distribution of the species by birds, wind, and water undoubtedly began very early, even before cultivation, and possibly before the existence of man in Asia or Europe. Grape growing was practiced very early in Palestine, and cultural material was transported by the early Phoenician navigators to the countries bordering on the Mediterranean Sea. According to Alphonse de Candolle, records of the cultivation of the grapevine and the making of wine in Egypt go back 5,000 to 6,000 years. Viticulture in Greece was flourishing during the time of Homer and must

[1]The writer wishes to acknowledge the cooperation of the many workers on grape breeding who have supplied the data on which a portion of this report is based. The following have supplied data relative to grape-breeding work in their respective countries: Ing. Fr. Landovsky, State Institute for Horticultural Research, Průhonice, Czechoslovakia; Dr. J. Dufrenoy, Station de Pathologie Végétale, Pont de la Maye, France; Prof. Giovanni Dalmasso, director, Stazione Sperimentale di Viticoltura e di Enologia, Conegliano, Italy; and Prof. Dr. Rudorf, director, Kaiser Wilhelm-Institut für Züchtungsforschung, Müncheberg, Germany. In the United States the following workers have furnished data on their grape-breeding investigations: H. P. Olmo, California Agricultural Experiment Station, Davis, Calif.; H. P. Stuckey, Georgia Experiment Station, Experiment, Ga.; A. L. Schrader, Maryland Agricultural Experiment Station, College Park, Md.; A. N. Wilcox, Minnesota Agricultural Experiment Station, St. Paul, Minn.; Paul H. Shepard, Missouri State Fruit Experiment Station, Mountain Grove, Mo.; Richard Wellington, L. M. Van Alstyne, and B. R. Nebel, New York (State) Agricultural Experiment Station, Geneva, N. Y.; F. E. Gladwin, Vineyard Substation of the State station, Fredonia, N. Y.; S. H. Yarnell, Texas Agricultural Experiment Station, College Station, Tex.; Fred W. HofMann, Virginia Agricultural Experiment Station, Blacksburg, Va.; C. A. Magoon and I. W. Dix, U. S Horticultural Station, National Agricultural Research Center, Beltsville, Md.; and Charles Dearing, Coastal Plain Branch Station, Willard, N. C.

have been known before his time. The Romans doubtless gained their knowledge of grape growing and the art of wine making from the Greeks. For a time the Romans seemed to prefer the Grecian product, and not until about the first century of the Christian Era did Italian wines begin to have a favorable reputation in their own region.

In the meantime French viticulture was originating in the vicinity of what is now Marseilles and spreading up the valley of the Rhone. In the second century A. D. it had spread along the banks of the Rhine. From a centralized beginning the growing of *Vitis vinifera* has gradually spread until at the present time it is grown commercially in parts of Europe, Asia, Africa, Australia, North America, and South America. Grape growing is practiced in the Northern Hemisphere mainly between 20° and 51° N. latitude, and varieties of *Vitis vinifera* are found in many of the countries bounded by these parallels. The most northern range of the varieties of *Vitis vinifera* is in the grape area of northern Germany, while the southern range extends into India. In the Southern Hemisphere, including Australia, South Africa, and South America, grape growing is carried on mainly between 20° and 40° S. latitude.

Introduction of Old World Grapes Into the United States

American colonists at a very early period understood the culture of the vine. The abundance of native grapevines along the Atlantic coast attracted their attention, but the first attempts, made early

THE *major portion of the grape-breeding work conducted by public institutions has been to improve quality, which is an elusive factor. The quality of our native varieties has been improved by crossing them with the best varieties of the European grape. Improvements in type of cluster and type of berry have been made by combining different native species. Rootstocks have been developed through hybridization which have suitable resistance to phylloxera, the deadly insect enemy of the grape, and are adapted to various soil types. Thus real progress has been made. But continued improvement is possible, and the results so far indicate that it can be obtained through hybridization. Grape breeding is relatively new, and there is need for more information on the inheritance of such characteristics as size, quality, seedlessness, cold hardiness, disease and insect resistance, and adaptability to environment. Rich collections of species and varieties are available as breeding material to bring about the further improvements that will result in increased consumption of grapes.*

in the seventeenth century, were with the vinifera or European grape. In 1619–21 the London Co., actively urging the culture of the vinifera grape as a source of revenue, brought French vine workers and collections of the best vinifera grape varieties of France to the settlements in Virginia. The Colonial Assembly was also active at the same time in encouraging and even ordering the care and cultivation of the vine. Similar attempts were made in the various colonies from New England to Georgia from 1619 to the beginning of the Revolutionary War.

Much has been written concerning these early attempts at growing vinifera grapes in eastern United States. The reports can be briefly summarized. The first year or two the vines gave considerable promise, then disease and insects appeared, resulting in dead vines and finally an abandoned vineyard. From present experience it would appear that lack of resistance to cold, insects, and disease in the northern regions, and susceptibility to disease and insect injury in the southern regions, were the factors responsible for the general failure of vinifera grape culture in eastern United States.

While failures were being recorded with vinifera grapes along the Atlantic coast, a start in their culture was being made on the Pacific slope in California. The Mission Fathers, going northward from Mexico, established the San Diego Mission in 1769. They brought grape material with them to plant at the various missions established from San Diego to Sonoma. The first plantings made were of a variety that became known as the Mission and represents earliest successful culture of vinifera grapes in the United States. Very little further development took place in California until after 1850. An essay by Col. Agostin Haraszthy on grape growing and wine making, published in 1858 and given wide circulation by the California State Agricultural Society, so stimulated viticulture in the State that 20,000,000 vines had been planted by 1862. Cuttings and rooted vines, including many of the better known varieties then grown in Europe, were introduced into California and distributed to growers. During the following years commercial grape growing, based entirely on vinifera grapes, developed rapidly. Production increased from 11,000 tons in 1869 to 360,000 in 1899, 1,827,000 in 1929, and 2,065,000 tons in 1935. Vinifera grape culture has also spread to other Western and Southwestern States. In favorable locations in Idaho, Washington, Oregon, Nevada, Arizona, Utah, New Mexico, and Texas, vinifera grapes prove profitable for local sale and, in special southern locations, for early commercial shipments.

Development and Early Improvement of American Native Grapes

After many failures with varieties of *Vitis vinifera* in the East, the native species were finally considered to be the best basis for an eastern grape industry.

Out of a planting of vinifera grapes made by the Kentucky Vineyard Society shortly after 1802, near the present site of Vevay, Ind., several varieties resisted unfavorable conditions better than others. One of these was called the Cape grape by John James Dufour II. This grape was later supposed to be identical with Alexander, a native

American vine, which had been planted in some way among the vinifera varieties. Later, from 1806 on, this native grape became generally distributed and was grown with apparent success. Grape authorities later considered the Alexander an offshoot of *Vitis labrusca* L., with a possibility of some vinifera species in its parentage. It probably originated along the banks of the Schuylkill in Pennsylvania, and its history antedates the Revolutionary War.

The next incentive to native grape growing came with the introduction of the Catawba variety. Its origin is uncertain. There is evidence that it originated in North Carolina. In 1819 John Adlum (1759–1836) obtained cuttings of the Catawba from a cultivated vine in Maryland for extensive nursery propagation in the District of Columbia. The cuttings of the variety were widely distributed by Adlum and some were sent to Nicholas Longworth (1783–1863) in Ohio, who became greatly impressed with it. During the period from 1825 to 1850 this variety, as well as Isabella and others less well-known, was planted in widely separated parts of the Eastern States. These two varieties were predominant until the introduction of the Concord, which originated from a chance seedling grown by Ephraim Wales Bull (1805–95), of Concord, Mass. The seed was planted in 1843 and produced fruit in 1849. The grape was named Concord and introduced in the spring of 1854. The Concord grew rapidly in popularity and its culture had spread to Missouri by 1855, 1 year after its introduction.

The improved varieties of native grapes introduced between 1800 and 1850 were principally chance seedlings or selections from wild native species. Since 1850 many men have been interested in grape breeding for the improvement of our native species.

Native species of *Vitis* are found in all parts of the United States. The fruit of many of them is of little direct value, but even the species producing poor fruit may have characters of value for hybridization and plant breeding. Some have been the source of our cultural varieties, while others are very valuable as stocks resistant to phylloxera and the root knot nematode. Table 1 indicates the main grape species that have been used in breeding work.

TABLE 1.—*Grape species possessing special breeding qualities*

Species, common name, and natural range	Character of vine	Resistance to— Phylloxera [1]	Cold [2]	Heat [2]	Wet [2]	Dry [2]	Qualities for breeding
Vitis aestivalis Michx; summer grape. New England to Georgia and westward to the Mississippi River.	Vigorous, climbing, leaves large, 20 cm, 3- to 5-lobed	14	VG	G	F	G	Resistance to fungus diseases; high sugar percentage; suitable wine properties; possible table use if crossed with large-berried varieties.
V. aestivalis var. *bourquiniana* Bailey (*V. bourquiniana* Muns.); Bourquin grape. Origin doubtful; adapted to Southeastern States.	Vigorous, climbing; leaves large, 3- to 5-lobed.	---	F	G	F	G	Vigor; disease resistance; productiveness; colored juice.

TABLE 1.—*Grape species possessing special breeding qualities*—Continued

Species, common name, and natural range	Character of vine	Resistance to— Phylloxera [1]	Cold [2]	Heat [2]	Wet [2]	Dry [2]	Qualities for breeding
V. berlandieri Planch.; Spanish grape, winter grape. Texas and northern Mexico.	Medium vigor, slender; leaves medium, 10 cm, 3-to 5-lobed.	19	F	G	F	G	Rootstock resistance to phylloxera; ability to grow on strong, limy soils.
V. candicans Engelm.; mustang grape. Mainly Texas, parts of Arkansas, Oklahoma, Louisiana, and Mexico.	Very vigorous, high climbing, leaves medium, nonlobed to 3-lobed.	15	F	G	F	G	Vigor for rootstock; easily hybridized; adapted to black limestone lands; large-berried fruit for wild vine.
V. champini Planch.; Champin grape. Mainly Texas.	Very vigorous, climbing; leaves medium, 10-12 cm, nonlobed to 3-lobed.	15	F	G	G	G	Vigor for rootstock; healthy foliage; wide adaptability; large-berried fruit.
V. cordifolia Lam.; frost grape. Wide range, from Great Lakes to Florida.	Vigorous, climbing; leaves medium, 10 cm.	18	G	G	G	G	Vigor; phylloxera resistance; wide natural range.
V. labrusca L.; fox grape. New England to northern Georgia, westward to Indiana, and bordering the Ohio River.	Medium vigor, climbing; leaves large, nonlobed to slightly lobed.	5	VG	F	F	F	Cold resistance; large-berried fruit; strong distinctive flavor.
V. linsecomii Buckl.; pinewoods grape, post-oak grape. Texas, parts of Louisiana, Oklahoma, Arkansas, and Missouri.	Vigorous, bushy to climbing; leaves very large, 3- to 5-lobed.	14	F	G	G	VG	Vigor; disease resistance; large clusters and berries; strong flavor.
V. longii Prince; Longs grape, bush grape. Parts of Arkansas, Oklahoma, Texas, New Mexico, and southeastern Colorado.	Very vigorous, bushy to climbing; leaves large, 3- to slightly 5-lobed.	14	G	G	VG	G	Vigor; phylloxera resistance; easy rooting of cuttings; vinous flavor.
V. monticola Buckl.; sweet mountain grape. Texas.	Medium vigor, slender, climbing; leaves small, nonlobed to slightly 3-lobed.	18	G	F	F	G	Phylloxera resistance; health of foliage; fruit medium to small.
V. rotundifolia Michx.; muscadine grape. Potomac River to Florida and west to eastern Texas.	Vigorous, slender, climbing; leaves small, not lobed.	20	F	G	F	G	Disease-resistant vine and fruit; special fruit flavor.
V. rupestris Scheele; sand grape. Southern Missouri and Illinois, Kentucky, Tennessee, Oklahoma, and eastern and central Texas to the Rio Grande.	Very vigorous, bushy, rarely climbing; leaves small, mostly nonlobed.	19	F	G	G	G	Phylloxera resistance; easy propagation; vigorous.
V. vulpina L.; riverbank grape. Canada to Texas and west to Great Salt Lake; wide range.	Vigorous, slender, moderately climbing; leaves large, mostly nonlobed, to slightly 3-lobed.	19	VG	F	G	F	Phylloxera resistance; cold resistance; easy propagation.
V. vinifera L.; European grape, wine grape. Introduced species.	Medium to strong vigor, bushy to climbing; leaves mostly 3- to 5-lobed, occasionally 7-lobed.	1	F	VG	F	G	Productiveness; high quality; easy propagation; some seedlessness.

[1] Ratings under phylloxera resistance are from 1 indicating greatest susceptibility to 20 indicating almost complete resistance.
[2] Symbols for resistance to cold, heat, wet soil, and drought are: VG=very good. G=good. F=fair.

One of the native species used extensively for breeding is *Vitis labrusca*, the fox grape. From chance seedlings of this species came Catawba and Concord, though they may also possibly have some

V. vinifera in their parentage. Through early hybridization work a number of popular varieties were obtained from *V. labrusca* crossed with *V. vinifera.* One of the earliest grape breeders in this country to utilize this cross was Edward Staniford Rogers (1826–99), of Massachusetts (fig. 1). Although engaged primarily in the shipping business with his father, he became interested in horticulture and conducted his experiments in grape hybridization in a garden on a city lot back of his home. In originating the group known as Rogers hybrids he used a large-fruited red labrusca known as Carter and fertilized the blossoms with pollen of two vinifera varieties, Black Hamburg and White Chasselas. From these crosses, made in 1851, he obtained about 150 seeds, which eventually produced 45 fruiting vines of high quality. These came into bearing between 1856 and 1858 and were numbered from 1 to 45 by Rogers. They were widely distributed, and some were finally named. Rogers continued his work and recrossed varieties already produced, but none of the later seedlings was promising enough to be introduced. This early work of Rogers indicated the value of *V. vinifera* in hybridizing to improve the quality of the native fruit. The Agawam variety is one of his main contributions that is still grown.

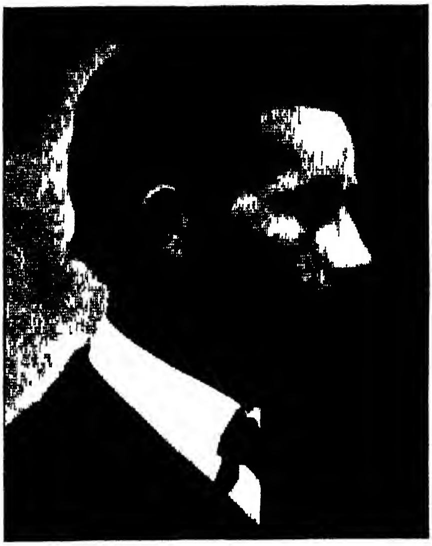

Figure 1.—**Edward Staniford Rogers, of Massachusetts, a pioneer in grape hybridization.**

Contemporary with Rogers were many other men who introduced hybrid varieties of their own breeding. Only a few of these can be mentioned here.

Andrew Jackson Caywood (1819–89), a nurseryman and fruit grower, became interested in grape breeding in New York. Little record of his methods remains. He differed from other grape breeders of his time, however, in concentrating on second-generation hybrids. The Dutchess represents one of his most important named varieties.

Charles Arnold (1818–83), of Canada, produced many seedlings. Since he lived near the northern limits of grape culture, he was interested mainly in producing cold hardiness in seedlings of high quality. His crosses were mainly a combination of *Vitis labrusca, V. vulpina* (the riverbank grape), and *V. vinifera.* His productions proved hardy under severe climatic conditions but were more or less susceptible to disease. Canada and Othello are two of his named varieties.

George W. Campbell (1817–98) conducted his grape-breeding work in Ohio and raised many seedlings. He used varieties mainly of *Vitis labrusca* and *V. vinifera* and to some extent *V. aestivalis* var.

bourquiniana (Munson) Bailey. Campbell Early represents his main contribution to present-day viticulture.

Louis Suelter, of Carver, Minn., carried on most of his hybridizing work between 1870 and 1884. Previous to this time he had grown many seedlings of the wild grape, *Vitis vulpina*. One of these seedlings appeared to blossom earlier and develop fruit color earlier than others. By crossing this with Concord as the pollen parent, four seedlings were produced and named Beta, Dakota, Monitor, and Suelter. These are reported to be hardy for the more northern and northwestern parts of the country, and they illustrate the use of *V. vulpina* in obtaining cold-resistant varieties.

James H. Ricketts (1818–1915), who conducted a bookbinding business in Newburgh, N. Y., became interested in grape improvement, and one of his first productions was Raritan. In order to utilize vinifera varieties to cross with native grapes he constructed a glasshouse for their culture. While his seedlings were not very vigorous, because of their large proportion of vinifera parentage, they were characterized by high quality and large cluster and berry. His crosses were mostly *Vitis labrusca* and *V. vinifera*. Some however, were complex hybrids, containing in addition either *V. aestivalis* (the summer grape) × *V. aestivalis* var. *bourquiniana* or *V. vulpina* parentage. Some of his named varieties include Downing, Empire State, and Jefferson.

Figure 2.—Thomas Volney Munson, of Texas, who did notable work in the botanical study and hybridizing of grapes. He originated and introduced many superior hybrid varieties, including varieties of the bunch type especially suitable for southern conditions.

Thomas Volney Munson (1843–1915, fig. 2) conducted most of his breeding work with grapes at Denison, Texas. The region in which he lived is rich in native species. Munson gave much of his time to the botanical study of grape species as well as to breeding and cultivating new varieties. In 1909 he published a summary of his extensive work with grape species, breeding, and the testing of grape varieties (*6*).[2] His work was largely instrumental in producing grape varieties of the bunch type suitable for southern conditions, where most of our varieties of northern parentage fail. Of particular interest and special value was his use of the native species *Vitis linsecomii*, the pinewoods grape, in the origination of hybrid varieties. By combining and selecting the vigorous, healthy native species Munson was able to originate fruiting varieties that are productive, vigorous, and better in

[2]Italic numbers in parentheses refer to Selected References on Grape Breeding, p 655.

fruiting qualities than the parental types. More hybrid grape varieties have been originated and introduced through his efforts than by any other agency in the United States.

Other grape breeders who have contributed some of our better known varieties include Joseph Backman, Hermann Jaeger, Jacob Moore, and Jacob Rommel.

Table 2 gives the parentage and origin, so far as they are known, of a number of the more important native American grape varieties. Some of the varieties that originated as chance seedlings, including Catawba, Concord, and Delaware, are among the most important commercial varieties at the present time. However, when varieties were needed for a specific purpose, such as hardiness, insect resistance, or improved quality, controlled crossing became necessary. The better known varieties are marked with an asterisk, and these can usually be obtained from some of the many commercial nurseries. Others are included as a partial list of varieties available for breeding purposes in State or Federal experimental plantings.

TECHNIQUE OF BREEDING

STRUCTURE OF GRAPE BLOSSOMS

TO UNDERSTAND the technique of breeding new grape varieties, some knowledge of the floral parts (fig. 3) is necessary. The blossoms of *Vitis* are arranged in a pyramidal, loosely branched cluster known as a panicle. In the wild state some vines may bear only male or staminate flowers, while others bear perfect or hermaphrodite flowers that have both stamens and pistils. American native species bear male flowers and hermaphrodite flowers on separate vines, while most European vines of *Vitis vinifera* bear only hermaphrodite flowers. The male flowers (fig. 3, *A*) differ from the hermaphrodite flowers in bearing well-developed stamens and only an incompletely developed pistil, which has no style or stigma and only a very small ovary, the ovules of which cannot be fertilized. The pollen grains of the male

flowers will germinate and can fertilize flowers that have a normally developed pistil.

The hermaphrodite blossoms range from flowers having reflexed, very poorly developed stamens (fig. 3, *B*) to perfect flowers with upright stamens (fig. 3, *C*). Varieties with reflex stamens usually do not set fruit, or set only very loose clusters, unless they are cross-pollinated, either naturally or artificially. Each individual perfect flower normally bears five stamens although the number may vary on the same flower cluster from four to eight. The stamen consists of the filament tipped by the anther containing a pair of pollen sacs. The stamens surround the fruit-producing part of the flower known as the pistil, which is made up of the stigma, a slender-necked style, and an enlarged ovary. The ovary contains the ovules which develop into seeds after fertilization has taken place.

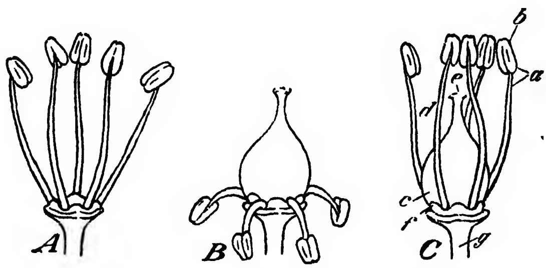

Figure 3.—Grape flower parts. *A*, Male flower. *B*, Flower with reflex stamens. *C*, Flower with upright stamens: *a*, Filament; *b*, anther; *c*, ovary; *d*, style; *e*, stigma; *f*, nectar gland; *g*, pedicel.

Previous to opening, these flower parts are enclosed in a cap-shaped united corolla (fig. 4, *A*). At the time of blossoming, the corolla is shed by becoming loosened at the base and coming off like a cap (fig. 4, *B*). When the flowers are in full bloom, each pollen sac of the anthers splits and sheds the pollen, which is in the form of small, ellipsoid, yellow grains. When moistened the grains take on a globular form. If examined microscopically, it can be noted that the pollen grain is enclosed in a cell wall with three thin-walled bands extending around the grain from pole to pole. In the middle of each of these bands is located a germinal pore through which the pollen tube will subsequently develop.

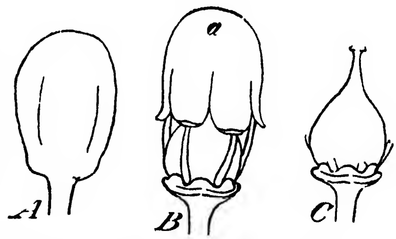

Figure 4.—*A*, Grape flower bud. *B*, Flower bud partly opened; *a*, corolla or cap. *C*, Emasculated flower.

The pollen grains are deposited on the stigma through natural or artificial means. If the stigma is receptive and the pollen grain viable, the pollen germinates and the pollen tube grows through the style, reaches the ovary, and enters an ovule through a small passage between its outer and inner coverings known as the micropyle. Fertilization then takes place by fusion of a sperm nucleus from the pollen tube with the egg nucleus in the ovule. The fertilized ovules become the grape seeds, and the ovary develops into the fruit or grape berry.

Method of Hybridizing

. The steps used in the actual hybridizing of grapes by various workers are more or less similar. After selection of the parent varieties, the flower clusters of the male or pollen parent are enclosed on the vine in sacks of paper, cellophane, or other material before any of the individual flowers have opened. This prevents contamination of the desired pollen by the pollen of other nearby varieties. As the blossoms open, the pollen remains within the sack and can be carried directly to the variety to be pollinated or gathered into a suitable container for future use.

The anthers are removed from flowers of the female parent before any pollen has been shed, and the emasculated cluster is enclosed in a bag to prevent the entrance of foreign pollen. At the time of pollination, the pollen from the selected male parent is brushed over the stigmas of the emasculated seed parent. When the fruit is ripe, the seeds are collected, washed, cleaned, and stored for future planting.

Time can be saved by germinating the seeds in a greenhouse. The young seedlings are usually transplanted to pots, cans, or a coldframe for growing one season before they are planted in the field for fruiting tests. The seedlings need some protection the first summer, varying with the climatic conditions under which they are grown. For field trial they are usually planted closer than in commercial vineyards, mainly to conserve space. From reports received, the distances vary from 6 inches to 4 feet in the row, with rows 5 to 12 feet apart. Fruiting may take from 2½ to 4½ years after the seedlings were set in vineyard form, or from 3½ to 5½ years from the time the seed was planted.

Recently a procedure that hastens the fruiting of grape seedlings has been followed at the United States Experiment Vineyard, Fresno, Calif. Grape seeds from controlled crosses in breeding work are planted in flats and started under greenhouse conditions about February 1. The seedlings are transplanted to 1-gallon cans after three or four true leaves are formed. During May and early June of the same season these seedlings attain a growth of from 12 to 16 inches. At this time three or four buds from the basal part of the seedling shoot can be obtained which are suitable for T budding. These seedling buds are T-budded into vigorous shoots of rootstocks or of bearing vines that are growing in vineyard form. With special care and training the seedling buds can be forced into growth. By the end of the first growing season, shoots from 6 to 12 feet long can be developed. At pruning time a cane 3 to 4 feet long can be left for next season's fruiting wood. At the Fresno station ripe fruit has been picked in August, 18 months from the time the seeds were planted in flats. This method saves at least 2 or 3 years compared with the usual method of fruiting grape seedlings. While it may not serve as a test of the commercial merits of a seedling, it does serve to determine many qualities such as color, shape, size, and flavor of the fruit. As with all breeding work, selection of desirable seedlings is necessary. A number of vines of each seedling must be grown and observations made of its commercial possibilities under various soil and climatic conditions before it can be introduced for commercial culture.

PRESENT GRAPE-BREEDING WORK IN THE UNITED STATES

In recent years hybridization of grape varieties and species has been actively carried on at Federal and State experiment stations. Most of the expansion has taken place since 1900, although a few of the State stations were engaged in grape breeding previous to that time. The most active interest has been evidenced since 1920. A recent survey indicates that in addition to the grape-breeding program of the Department the following State stations are conducting grape-breeding work: California, Georgia, Maryland, Minnesota, Missouri, New York, South Dakota, Texas, and Virginia.

The principal objectives have been improvement in fruit quality, productivity, disease resistance, and adaptability to soil and climatic conditions. The work is being carried on with three distinct types that are of commercial importance in the United States—the American native bunch grapes, the muscadine grapes, and the European or Old World grapes.

Native Bunch Grapes

The native bunch grapes have been developed from various native species, in many cases with the infusion of the European grape through natural or controlled hybridization. The species from which the varieties of this group have been derived rank in importance in the following order: *Vitis labrusca*, *V. vinifera*, *V. aestivalis*, *V. linsecomii*, *V. vulpina*, *V. aestivalis* var. *bourquiniana*, *V. champini*, *V. rupestris*, *V. cinerea*. This group, represented commercially by such varieties as Beacon, Catawba, Concord, Cynthiana, Delaware, Iona, Lenoir, Niagara (fig. 5), and others of lesser importance, is grown, at least for home consumption, in every State in the Union. Commercial production is principally in the North Atlantic States, the Great Lakes region, the Central States, and to a lesser extent in the South and in the Pacific Northwest. They are used for table, local markets, shipment for some distance, unfermented juice, and wine. The vines of this type are characterized by medium to vigorous growth; the leaves are medium to large, three- to five-lobed or entire; the tendrills are forked; and the fruit clusters are small to above medium in size. The individual berries of different varieties vary in outline from globular to ovoid. The skin separates easily from the pulp, while the seeds are firmly retained in the pulp. The varieties that have *V. labrusca*, or fox grape, parentage are characterized by what is called a foxy flavor, which is very important in the manufacture of unfermented juice.

The trend of grape breeding with the native bunch grapes has been to improve quality by crossing with varieties of *Vitis vinifera*. This has been successfully done by the New York (State) Agricultural Experiment Station, which has introduced 21 named seedlings for commercial trial. The northern species, *V. labrusca* and *V. vulpina*, have been utilized by the Minnesota and South Dakota Stations to develop varieties with cold hardiness for the northern regions. Size of berries has been increased by the use of *V. labrusca*. Cold hardiness and adaptability have been developed by the use of *V. vulpina*. Thirty-two named seedlings have been introduced by the South

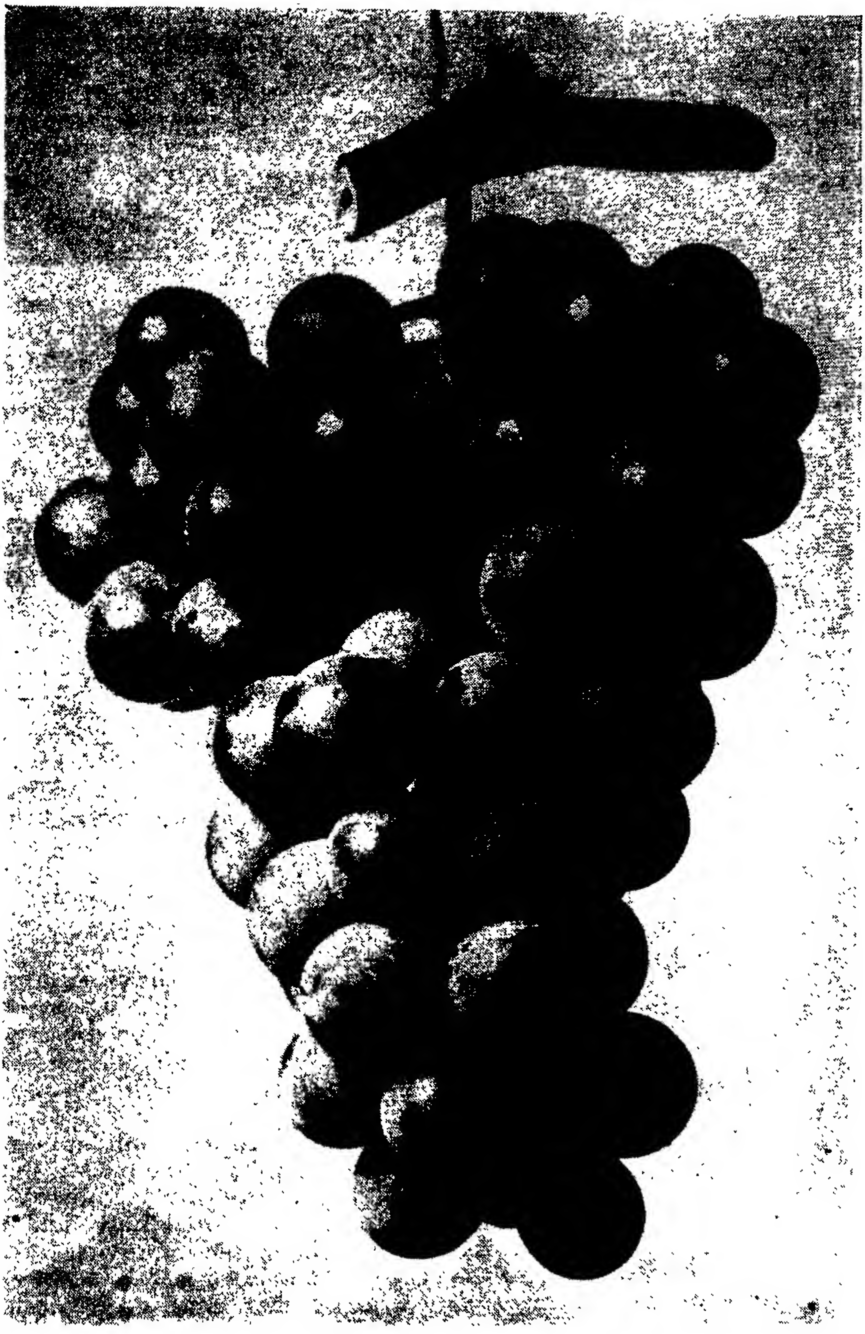

Figure 5.—The Niagara, one of the high-quality grape varieties developed from American species.

Dakota Station. The stations of Maryland, Missouri Texas, and Virginia, and the United States Department of Agriculture at Beltsville, Md., are conducting grape-breeding work to improve the quality and adaptability of the native bunch-grape types by crossing varieties containing labrusca and vinifera parentage with varieties developed from more southern species, such as *V. aestivalis*, *V. aestivalis* var. *bourquiniana*, *V. champini*, *V. linsecomii*, and *V. rupestris*.

Desirable Objectives in Breeding American Bunch Grapes

In the United States the desirable objectives in breeding the American bunch grapes vary with the regions in which they are grown, and regional needs must be studied separately. Three main regions are involved: (1) The North Atlantic States, the grape-growing areas along the Great Lakes, and the North Central States; (2) the Southern States; and (3) the northern Great Plains.

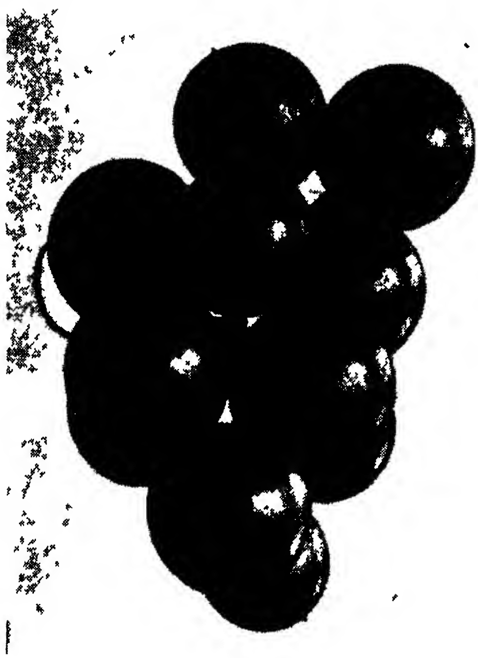

Figure 6.—A typical cluster of muscadine grapes, Scuppernong variety.

In the first region it would seem desirable, in the case of table grapes, to combine increased production with increased size of cluster and berry. In quality, the strong flavor of the labrusca may be ameliorated by the addition of the rich vinous flavor of the vinifera. The skin should be more edible and the flesh more melting than is the case with the Concord type if these qualities can at the same time be combined with improved shipping and handling qualities. The sugar content could be increased and the acidity adjacent to the seeds decreased. The seeds should separate readily from the pulp. It may not be too much to hope that the seeds can at some future time be entirely eliminated. In the case of varieties for unfermented juice, increased productiveness, a more highly colored juice, and a more melting pulp would seem desirable. Desirable improvement in varieties for wine varies with the type of wine. In general, increased sugar content, more juice production, and earlier maturity are desirable objectives. The development of a more vigorous, hardy, disease-resistant, and insect-resistant root system would materially aid the industry as a whole.

In the second region, the Southern States, important consideration should be given to resistance to disease and insect injury, principally downy mildew (*Plasmopara viticola* (Berk. and Curt.) Berl. and DeToni), black rot (*Guignardia bidwellii* (Ell.) Viala and Ravaz), root rot, and phylloxera injury. Improved size of berry and better quality would seem desirable. Varieties adapted to the various soil and climatic conditions would be of great assistance to the industry in this region.

In the third region, the northern Great Plains, cold hardiness must of necessity be of primary importance. It would seem possible to combine the cold hardiness of the more northern species with the

Figure 7.—Flower clusters of muscadine grapes. Upper three clusters, staminate blossoms; lower three clusters, pistillate or fruit-bearing blossoms.

size and quality of some of the improved varieties. Some of the more hardy vinifera varieties that mature in a short growing season may be hybridized with the more hardy native species to promote both early maturity and improved quality.

Muscadine Grapes

The muscadine grapes are especially adapted to the Southeastern and Gulf States. Selections have been made from chance seedlings and from the native wild vines of *Vitis rotundifolia*, the muscadine grape. This type of grape is represented commercially by the varieties Eden, James, Mish, Thomas, Scuppernong (fig. 6), and

others less prominent. They are used for table, local markets, juice, and wine. The vines of this type are characterized by vigorous growth, small, nonlobed leaves, simple tendrils, and small fruit clusters, sometimes with only a few berries. The adherence of berry to pedicel is generally poor. The individual berries are globular. The skin is mostly tough and leathery and separates readily from the pulp. The seeds are large and firmly embedded in the pulp. The strong musky flavor is very characteristic.

The present commercial varieties of muscadine grapes are not self-fertile (fig. 7). In commercial plantings it is necessary to include male vines to pollinate the fruiting varieties. Through crosses and selections by the Department at Willard, N. C., a number of self-fertile varieties have been produced. The breeding work at this station has concentrated on the production of these self-fertile, perfect-flowered types. Hybrids have also been obtained between the muscadine grapes and the European and the American bunch-type grapes. The Georgia Experiment Station has also been conducting breeding work with muscadine grapes for improvement in vine and fruit qualities. Eleven muscadine varieties having improved characters have been introduced for commercial trial by the Georgia Station.

Desirable Objectives in Breeding Muscadine Grapes

The muscadine grapes normally have a high resistance to disease and insect injury, and these qualities should be retained. It is desirable to combine quality and size of fruit with the perfect- or hermaphrodite-flowered types. The bunch size might be increased and adherence of the berry to the pedicel developed. The skin might be made more tender and the sweetness and flavor ameliorated by crossing with other grape species. The seeds of the muscadine grapes are larger than those of any other native species, and the development of varieties with smaller seeds would be a decided improvement.

European or Vinifera Grapes

The European or Old World grape types have been developed from the one species, *Vitis vinifera*. The vinifera grape industry in the United States, representing approximately 90 percent of the total commercial grape production, is centered in California, with local plantings in other Western States. The vines of this type are stocky and vigorous to very vigorous in growth. The leaves are medium to very large and usually characteristically lobed. The fruit clusters vary widely with the variety, from very small to very large. The individual berries range from small, as in the seedless currant type, to very large in the table varieties. While the more typical shape of the berries of this type is ovoid, there are globular and elongated forms. The skin adheres to the pulp, whereas the seeds separate readily from the pulp. Some varieties, such as the currant and seedless raisin types, develop without seeds. The fruit is characterized by a relatively high sugar content and a rich vinous flavor. There are types suitable for table use, distant shipping, storage, raisins, juice, and wine (fig. 8). Numerous varieties have been imported from foreign sources for trial in the United States, and of course all of our present commercial vinifera varieties are of foreign origin.

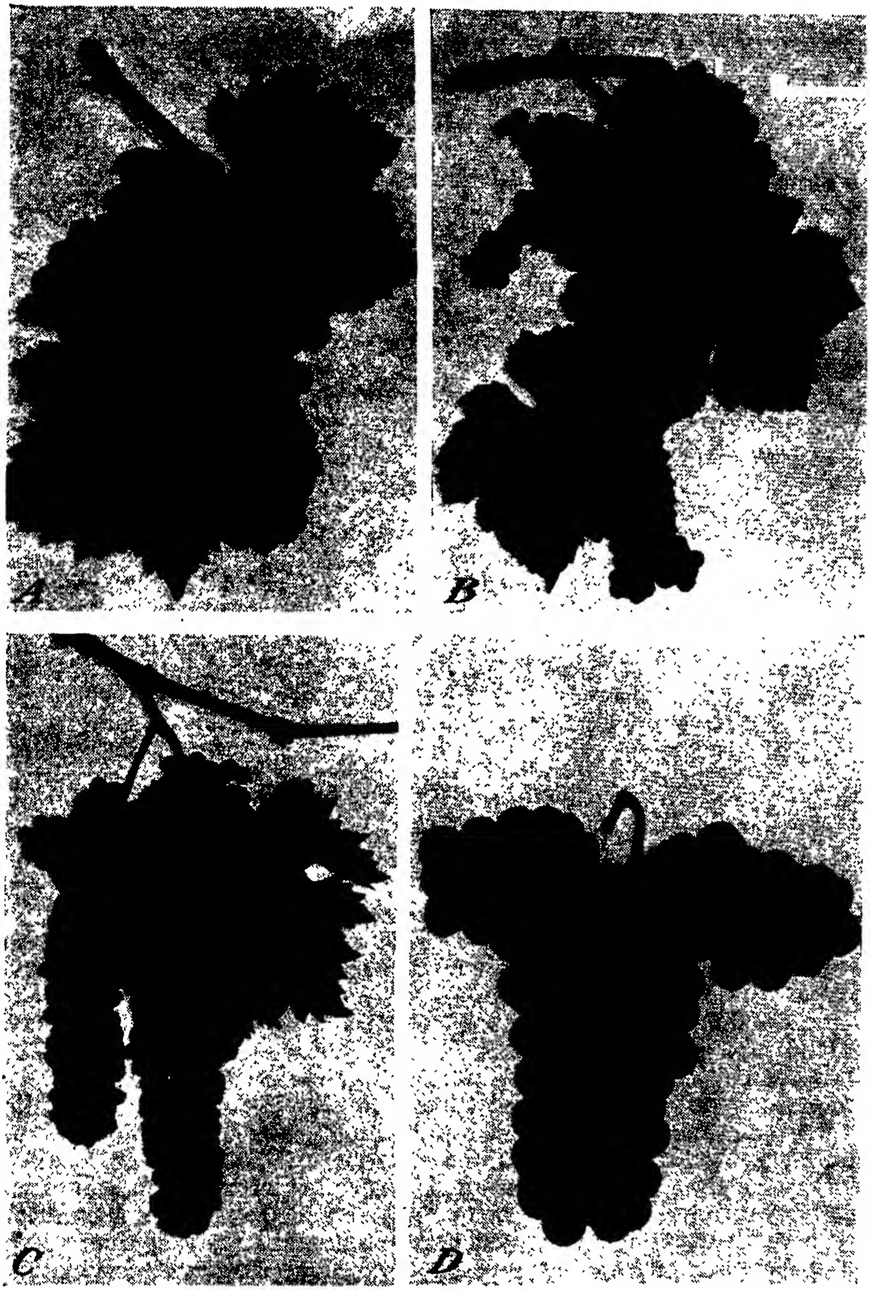

Figure 8.—Typical vinifera grape varieties: *A*, Flame Tokay, table type; *B*, Sultanina (Thompson Seedless), seedless raisin type; *C*, Panariti, currant raisin type; *D*, Petit Syrah, wine type.

The important table varieties are represented by Alexandria (Muscat of Alexandria), Alphonse Lavalle (Ribier), Castiza (Red Malaga), Emperor, Flame Tokay, Malaga, Ohanez, Olivette Blanche, Olivette Noire, and Sultanina (Thompson Seedless). The chief raisin varieties grown are Alexandria, Panariti (Zante currant type), Sultana, and Sultanina. There are many varieties utilized for wine manufacture. The white varieties used for wine include Alexandria, Burger, Chasselas de Fontainebleau, Feher Zagos, Franken Riesling, Gewürz Traminer (pink), Green Hungarian, Muscadelle du Bordelais, Muscat de Frontignan, Palomino, Pedro Ximines, Sauvignon Blanc, Sauvignon Vert, and Semillon. The black varieties include Alicante Bouschet, Aramon, Barbera, Cabernet Sauvignon, Carignane, Cinsaut, Grenache, Mataro, Mission, Mondeuse, Petit Syrah, Refosco, St. Macaire, and Zinfandel.

The trend in vinifera grape breeding in the United States has been to produce more seedless types and improved table, raisin, and wine varieties. Breeding work is being conducted by the Department at Fresno, Calif., and by the California Agricultural Experiment Station at Davis.

At the United States Experiment Vineyard, Fresno, Calif., approximately 500 seedlings have fruited, and seedless-type seedlings have been produced. Earlier maturity has been promoted by crossing early-ripening varieties. Richness of flavor has been transmitted by muscat-flavored varieties. Large-sized berries and a wide range of berry forms have been obtained. Seedlings with red juice adaptable to unfermented juice and to wine manufacture have been produced. Selections have been made of the most promising types for further production tests.

Desirable Objectives in Breeding Vinifera Grapes

In the United States the desirable objectives in breeding vinifera grapes vary with the purpose for which the fruit is intended. The type may be divided into table, raisin, and wine groups, although some varieties may be used interchangeably.

The table group is made up of varieties used locally, shipped to distant markets, and held in cold storage for later use. Since the major portion of the table-grape crop must be shipped from California to the distant eastern markets, firmness of fruit and adherence of berry to pedicel are of primary importance. These qualities are possessed by most of the present shipping varieties. The quality of these table varieties might be improved by the infusion of some of the aroma and flavor of the muscat-flavored grapes. Seedlessness in table grapes has become an important factor. While some seedless varieties are available at present, improvements are possible in size, adherence to stem, quality, color, and extended season of maturity. Improved early- and late-ripening grapes would have a distinct value in prolonging the market season. A storage grape of fine eating quality would be of great value. An assortment of black, red, and white grapes ripening from early to late would supply a demand that is not filled at the present time.

The raisin-grape group at the present time consists of currant-type, seedless-type, and muscat-type varieties. A currant-type

variety with the addition of muscat flavor that would be productive without the annual ringing or cutting of the bark, which is now necessary, would be a decided improvement over present varieties. The present seedless-type raisin varieties could well be increased in size and improved in flavor. A large-sized, seedless, muscat-flavored variety would be very valuable to the raisin industry. A seeded muscat type that would set well-filled, uniform clusters would be a valuable improvement.

In the wine group, many varieties are utilized to make the various kinds of wine. To make certain wine types, the juice of several varieties, often three or more, is blended. It would seem to be within the realm of possibility to blend the varieties by breeding to produce a single variety with all the requirements for a particular kind of wine. Varieties with improved flavors and juice of a more intense and lasting color might be developed. At present all vinifera varieties must be grafted on roots resistant to phylloxera. Some day, varieties resistant to phylloxera, with fruit of desirable quality, may be developed so that grafting will not be necessary. The legalized sale of wines has, of course, furnished an incentive to produce a better product, and this will ultimately result in a greater demand for improved varieties for wine purposes.

EARLY IMPROVEMENT OF GRAPES IN EUROPE

As previously stated, the history of *Vitis vinifera*, the European grape, begins in prehistoric times. During this long period, selection was undoubtedly largely responsible for the numerous varieties concerning the origin of which we have no definite information. Early hybridization work with this species was started by Louis and Henry Bouschet in 1828. Their crosses were made with the definite object of combining the intense color of the Tinto with the high yield of varieties in southern France. Their efforts resulted in the production of three varieties, Alicante Bouschet, Petit Bouschet, and Grand Noir de la Calmette, which are still of commercial importance.

In France, hybridization of native American species assumed very great importance after phylloxera had made the grafting of vinifera varieties on resistant roots necessary. Between 1860 and 1870, diseased spots were noted in many French vineyards. The weakening of the vines was found to be caused by an insect (*Phylloxera vitifoliae* Fitch) living on the roots. Winged forms of the insect, which cause the formation of galls on the leaves, were also found. The phylloxera is indigenous to the eastern and central United States and probably was carried to France before 1860 on rooted American vines imported to resist damage then being caused in Europe by powdery mildew (*Uncinula necator* (Schw.) Burr). Phylloxera spread rapidly over France and the adjacent vine-growing countries. In order to save the vinifera vineyard industry from complete destruction, it was found necessary to graft the European varieties on native American rootstocks, which were resistant to the phylloxera insects. The United States thus furnished both the disease and the cure. Since the American grape species varied in their adaptability to the soil and climatic conditions of Europe, hybrids between American species

138904°—37——42

and hybrids between European and native American grapes were utilized for phylloxera-resistant rootstocks.

Some breeding work to combine American and European vines had been started previous to 1876 by the School of Agriculture at Montpellier, France. Foëx, Millardet, Viala, Ravaz, de Grasset, Ganzin, Couderc, Castel, and Seibel practiced similar hybridizing work, which resulted in producing many rootstocks resistant to phylloxera and adapted to different soil types. Direct-producing varieties were also sought that would combine the resistance of the American species with the fruit qualities of *Vitis vinifera*. Many direct-producing varieties were originated through breeding. While the efforts were most successful in producing resistant rootstocks that are used today in the vinifera regions of foreign countries as well as the United States, ideal direct-producing fruit types were not obtained. A start was made, however, which may eventually bring results.

Phylloxera infestations occurred early in the commercial vinifera plantings in California. The only present method of control that has general application is the use of resistant rootstocks on which the vinifera grape varieties are grafted. These rootstocks are of American species and hybrids of American species, though the actual development of them occurred in Europe where phylloxera ravaged the vineyards before it became serious in California. Up to this time, the vinifera grape industry in the United States has depended for stocks on these species selections and hybrids made in Europe. The adaptability of the stocks to the various soil and climatic conditions and their suitability for the vinifera varieties in the United States have been tested by Federal and State workers. Breeding work is now under way for the production of improved stocks for the vinifera regions of the United States.

PRESENT GRAPE-BREEDING WORK IN OTHER COUNTRIES

Czechoslovakia

Investigations in grape breeding in Czechoslovakia are under the direction of Albert Stummer in Nikolsburg and Dr. Franz Frimmel in Brünn. This work, located at the extreme northern edge of commercial grape growing in Europe, includes the testing of resistant stocks, hybridization of varieties to secure wine and table grapes well adapted to northern production, and related investigations. Crossing and selfing of many varieties has been done.

France

French investigators, through selecting and breeding rootstocks resistant to phylloxera and congenial to vinifera varieties, saved the industry of Europe after phylloxera was introduced. A number of privately supported experimental vineyards, as well as a few publicly supported research stations, are still working on resistant understocks. also on hybridizing American species with vinifera varieties to secure varieties sufficiently resistant to grow on their own roots and be resistant to downy mildew (*Plasmopara*) and that will produce fruit of value. Work of this type is under way in the Cognac region.

Germany

Grape breeding is conducted at several points in Germany, as follows:

Alzey Grape Experiment Station (Leader, Grape Inspector Scheu).—Crosses are made with the objective of securing early-ripening and vigorous, good-quality wine grapes and also a series of table-grape varieties ripening from early until extremely late that are well adapted to the Rhineland area. From 15,000 cross-bred seedlings, 450 selections are being tested.

Freiburg; Badisches Weinbauinstitute (Director, Dr. Muller)—Breeding investigations are to secure varieties giving very high wine quality. Crosses of Sylvaner × Rülander have given exceptional wine quality and are being tested on various rootstocks. Resistance of varieties to downy mildew and the development of varieties having dark-red juice are other objectives. Twenty-five selections producing dark-red wine have been made.

Geisenheim a. Rh.; Versuchs- und Forschungsanstalt fur Wein-, Obst- und Gartenbau (Director, Prof. Dr. Rudloff; in charge of grape investigations, Dr. Birk).—The work includes attempts at improvement of the varieties through clone selection; the breeding and testing of phylloxera-resistant rootstocks having good adaptation and an affinity to the important varieties and that are resistant to diseases; and the breeding of early- and late-ripening, high-quality table grapes.

Muncheberg; Kaiser Wilhelm-Institut fur Zuchtungsforschung (Director, Prof. Dr. Rudorf; in charge of grape investigations, Dr. Husfeld and Dr. Scherz).—Investigations are primarily to develop disease-resistant and insect-resistant rootstocks, vines, and varieties. Seedlings are grown by the hundreds of thousands and exposed to disease infection. Fifty thousand seedlings resistant to *Plasmopara* have been found. Their stock compatability and value for wine remain to be tested.

Weinsberg; Wurttembergische Anstalt fur Rebenzuchtung und Rebenpfropfung (Leader, Mr. Herold).—The work consists primarily of the testing of understocks against phylloxera and the development by hybridization and testing of red-wine varieties.

Wurzburg; Staatliche Hauptstelle fur Rebenzüchtung (Leader, Dr. Ziegler).—Breeding investigations include clone selection and hybridization between grape varieties. Some 200 prospective varieties from crosses between varieties are now under test. Breeding of rootstocks resistant to *Plasmopara* and phylloxera, and showing good affinity with varieties, has resulted in about 1,500 selections that appear resistant and are receiving further test. Development of direct producers that combine resistance to phylloxera and diseases with good fruit and wine characteristics is also being attempted.

Italy

Grape-breeding experiments have been actively conducted at various places in Italy. Special attention has been given to the hybridizing of American vines for rootstocks. F. Paulsen, A. Ruggeri, C. Grimaldi, and C. Montoneri, working principally in Sicily, have produced hybrids of American vines for rootstocks. Some of the

more promising productions are Paulsen hybrids (*Vitis berlandieri* × *V. rupestris*) Nos. 771, 775, 779, and 1103; (*V. berlandieri* × (*V. riparia* × *V. rupestris*)) No. 1120; (*V. berlandieri* × (Aramon × Rupestris Ganzin)) No. 1045; (*V. berlandieri* × (Mourvedre × *V. rupestris* 1202)) No. 1323; Ruggeri hybrids (*V. berlandieri* × *V. rupestris* du Lot) No. 140; (*V. berlandieri* × *V. riparia*) Nos. 225, 240, and 325. Other hybrid rootstocks have been originated in Puglia by G. Ceccarelli and V. Prosperi.

Breeding for better table-grape varieties has been conducted by Alberto Pirovano, director of the Institute of Fruit Culture and Electogenetics at Rome. Crosses and backcrosses have been made with a number of vinifera varieties. Amòng the most interesting and noteworthy seedlings produced are Primus, Termidoro, Delizia di Vaprio, Italia, Aurora, Galvani, Perlona, Angelo Pirovano, Teresa Pirovano, and Principessa di Piemonte.

V. Prosperi, director of the Royal Nursery of American Vines at Velletri, has also obtained some interesting table-grape seedlings. Of special note are No. 167 (Moscato de Terracina × Chasselas Vibert) and No. 8 (Panse Precoce × Moscato Fior d'Aranico).

The Royal Experiment Station of Viticulture and Oenology of Conegliano, founded in 1923, began hybridizing work with *Vitis vinifera*. Particular attention has been given to the production of new types of wine and table grapes with regard to their adaptability to the natural conditions of northern Italy. The work of this station was planned by Director G. Dalmasso and L. Manzoni. Italian and French varieties of *V. vinifera* have been used in the grape-breeding work. Better types have been secured so far from crosses of Trebbiano × Traminer, Prosecco × Cabernet Sauvignon, Trebbiano × Verdiso, and Besgano × Moscato de Amburgo. More recently the Conegliano station has started hybridization of *V. vinifera* with American vines, and hybridizing American vines, for the production of new rootstocks more adapted to conditions in the Province of Venezia.

Union of Soviet Socialist Republics

The following outline of the grape investigations in the Union of Soviet Socialist Republics has been taken from Plant Breeding in the Soviet Union, by N. I. Vavilov, published by the Imperial Bureaux of Plant Genetics, Cambridge and Aberystwyth, 1933. Fourteen plant-breeding centers, covering every section of the Soviet Union, constitute regional headquarters for breeding work covering all agricultural crops. These are all under the direction of the Institute of Plant Industry, N. I. Vavilov, director. The grape program includes the following:

(1) Immunity: (*a*) Phylloxera. Breeding resistant varieties by method of cyclic crossing of *Vitis vinifera* with American species and obtaining generations up to F_2 and F_3 (with study of characters of phylloxera). (*b*) Mildew. Breeding resistant varieties by method of cyclic crossing of *V. vinifera* with American species (obtaining generations up to F_2 and F_3, and study of resistance to mildew). (*c*) *Oidium*. Breeding resistant forms by method of cyclic crossing of *V. vinifera* with American species (obtaining generations up to F_2 and F_3, and study of resistance to *Oidium*).

(2) Resistance to frost and cold. Breeding resistant varieties by means of *Vitis vinifera* × *V. amurensis* with study of this character.

(3) Vegetative period. Breeding early and later varieties (in order to extend their cultivation northward) by means of intercrossing of *V. vinifera* and also by crossing with other *Vitis* species.

(4) Chemical characters. Breeding of dessert varieties with transportability, varieties for wine and alcohol-free beverages (sugar and acid content).

(5) Specific characters: (*a*) Preliminary work, on study of characters related to transportability and storing; (*b*) study of seedless varieties in order to obtain productive seedless strains; (*c*) study of character of rooting in *Vitis*.

(6) Problem of sex. Study of heredity of sex in order to obtain self-fertile varieties.

(7) Self-sterility and self-fertility. Study to improve yield.

(8) Permanent modifications. Genetic study (yield of quantitative characters).

(9) The origin of cultivated plants. Comparative genetics of wild *Vitis* species.

(10) Chimeras: (*a*) Study of chimeras in order to find agriculturally valuable characters; (*b*) production of chimeras of practical value; (*c*) qualitative inequality of ontogenetic system of individuals.

Vitis should be included in studies of inbreeding.

Phytopathology and entomology: Methods of inoculation of seedlings with phylloxera, downy mildew, and *Oidium*. Testing of seedlings for resistance to phylloxera under various ecological conditions.

Physiology Stimulation of seedlings and seeds to accelerated growth and fruit bearing.

Australia

The Department of Agriculture, New South Wales, Australia, at its Yanco Experiment Farm, started grape breeding in 1928, under the direction of H. Wenholz, to produce a black table grape of high quality and with the shipping quality of Ohanez. Breeding for disease resistance and for the production of seedless raisin and table varieties has been in progress.

ACHIEVEMENTS AND NEEDS

The major portion of the grape-breeding work has been to improve quality. Quality is an elusive factor. In quality of fruit, native American types are considered inferior to the vinifera types. The quality of fruit has been improved where our native varieties have been crossed with the best-quality varieties of *Vitis vinifera*. Improvements in cluster and berry types have been made by combining different native species. Grape rootstocks have been developed through hybridization which have suitable resistance to phylloxera and are adapted to various soil types.

The results so far obtained indicate that grape improvements can be obtained through hybridization. The field of grape breeding is still relatively new. There is need for more information, especially on the inheritance of desirable characters such as size, quality, seedlessness, cold hardiness, disease and insect resistance, and adaptability to environment. Collections of species, native American varieties, and European varieties are available as breeding material. Progress has been made, but continued improvement is possible. Better quality, more attractive appearance, and a prolonged season will result in increased demand and consumption, to the ultimate profit of the grape industry.

INHERITANCE IN GRAPES [3]

Early grape breeding was carried on mainly to obtain desirable varieties or stocks, and little attention was given to the study of inherita-

[3] The following pages are written primarily for students and others professionally interested in breeding or genetics

ble qualities. As intensive breeding work has been in progress a relatively short time, and the time necessary from seed to fruit in one generation of grapes occupies ordinarily from 3½ to 5½ years, only limited data are available on the transmission of inheritable qualities. Genetic and cytological research projects at State and Federal institutions are listed in the appendix material.

The somatic chromosome number of most vinifera grapes and most American bunch-grape species is 38. Gigas forms of American and vinifera varieties are tetraploids with 76 chromosomes in the somatic tissues. Most American bunch-grape species will cross readily with one another and with vinifera varieties, forming fully fertile hybrids. The two muscadine species cross freely with each other, with fertile hybrids resulting. The muscadines and vinifera varieties or American bunch-grape types are crossed with some difficulty, and the F_1 hybrids of these crosses generally set but few if any fruits.

One important commercial consideration concerns the character of grape flowers—whether the stamens are upright or reflex. At the New York (State) Agricultural Experiment Station, crossing two varieties with reflex stamens gave in the F_1 a ratio of 1 reflex to 1 upright in the resultant progeny. Crossing upright stamens with reflex stamens gave the same ratio, while crossing two varieties with upright stamens gave 4.3 upright to 1 reflex in the F_1 progeny. From crosses of vinifera varieties with upright stamens at the United States Experiment Vineyard, Fresno, Calif., the ratio of upright to reflex stamens in the F_1 seedlings was 5.4 to 1.

In color of fruit, white is a recessive character, and only white-fruited progeny results when two white-fruited varieties are crossed. Both red and black are dominant over white, and most of the red and black varieties studied appear to be heterozygous for color.

The investigations of Hedrick and Anthony (*5*) at Geneva, N. Y., reported in 1915, relative to color, indicated that crosses of black-fruited and white-fruited varieties gave in the F_1 approximately 3 black-fruited seedlings to 1 white-fruited. Black-fruited and red-fruited varieties segregated into these colors only when selfed or crossed. At the United States Experiment Vineyard at Fresno, Calif., the segregation obtained in the first and later generations of crosses among varieties with colored fruit has varied with the different parent varieties used. It would appear that the majority of colored grapes on which data are available are heterozygous for both red and black color.

During recent years attention has been given to the origination of more seedless varieties of grapes through breeding. A. B. Stout, of the New York Botanical Garden, in cooperation with the New York (State) Agricultural Experiment Station, has produced seedless or near-seedless types by using the pollen from the present seedless vinifera varieties to pollinate American-type varieties. At the United States Experiment Vineyard, Fresno, Calif., crosses have been made between the seedless vinifera varieties and many of the seed-bearing vinifera varieties. Of the seedlings that have fruited to date, 12.4 percent have produced seedless-type fruit in the F_1 generation. The production of seedlessness in the F_1 generation has proved the value of seedless varieties as male parents to produce new seedless types.

While the inheritable factor for seedlessness has not been determined, progress has been made in developing more seedless varieties for breeding work, some of which may also be of commercial value.

Summary of Present Grape Breeding in the United States

California

Main grape breeding work started in 1931 to produce new seedless varieties, improve the quality of table varieties, and to study genetic factors. Crosses and selfed varieties have yielded approximately 3,000 seedlings. The chromosome number for Sultanina was found to be 38 and of the Gigas types to be 76. Breeding material includes a large number of vinifera varieties and a collection of native American species. Selfed seedlings are being grown of the following varieties: Alexandria (Muscat of Alexandria), Alphonse Lavallee (Ribier[4]), Angulato, Black Corinth, Chaouch, Chasselas Cioutat, Diamond Jubilee, Emperor, Flame Tokay, Gros Colman, Hunisa × Muscat, Malaga, Malvasia Bianca, Molinera, Muscatello Fino, and Ohanez.

Seedlings have been obtained from the following crosses: Alexandria × Black Corinth, Alexandria × Sultana, Alexandria × Sultanina, Alexandria × Sultanina Gigas, Alexandria × Sultanina Rosea, Alexandria × White Corinth, Alphonse Lavallee × Monukka, Alphonse Lavallee × Sultana, Alphonse Lavallee × Sultanina, Alphonse Lavallee × Sultanina Gigas, Augibi × Sultanina, Black Morocco × Golden Muscat, Burgrave × Monukka, Burgrave × Sultanina, Chaouch × Alexandria, Chaouch × Black Corinth, Chaouch × Monukka, Chaouch × Sultana, Chaouch × Sultanina, Damas Rose × Monukka, Damas Rose × Sultanina, Damas Rose × Sultanina Gigas, Dattier de Beyrouth × Monukka, Dattier de Beyrouth × Sultanina, Diamond Jubilee × Monukka, Diamond Jubilee × Sultanina, Emperor × Monukka, Emperor × Sultanina, Flame Tokay × Black Corinth, Flame Tokay × Monukka, Flame Tokay × Sultana, Flame Tokay × Sultanina, Flame Tokay × Sultanina Rosea, Flame Tokay × White Corinth, Golden Muscat × (Hunisa × Muscat), Golden Muscat × Sultanina, Gros Colman × Monukka, Gros Colman × Sultanina, Gros Colman × Sultanina Gigas, Gros Colman × Sultanina Rosea, Henab × Monukka, Hunisa × Black Corinth, Hunisa × Golden Muscat, Hunisa × Monukka, Hunisa × Sultanina, Hunisa × Sultanina Gigas, (Hunisa × Muscat) × Golden Muscat, (Hunisa × Muscat) × Malvasia Bianca, (Hunisa × Muscat) × Alexandria, Madeleine Angevine × Luglienga, Madresfield Court × Monukka, Madresfield Court × Sultanina, Malvasia Bianca × Sultanina, Marvel de Vaucluse × Malvasia Bianca, Molinera × Monukka, Molinera × Sultanina, Muscat Blowers × Monukka, Muscat Blowers × Sultanina, Muscat Bowood × Black Corinth, Muscatello Fino × Sultanina, Muscat Gigas × Alexandria, Muscat Hamburg × Sultanina, Olivette Blanche × Monukka, Olivette Blanche × Sultanina, Rambela × Monukka, Rambela × Sultanina, Trivoti × Monukka, Trivoti × Sultanina, Zabalkanski × Monukka.

Georgia

Grape-breeding work is entirely with *Vitis rotundifolia* to improve vine and fruit qualities of the muscadine grapes. Eleven varieties have been introduced from 1919 to 1934. Breeding material includes a number of muscadine varieties and station seedlings. Table 3 gives the varieties introduced.

Table 3.—*Grape varieties introduced by the Georgia Experiment Station*

Variety	Year introduced	Parentage	Qualities
Brownie	1933	San Monta × white male	Productive; high sugar content.
Dulcet	1934	Hunt × white male	
Howard	1921	Scuppernong × black male	High sugar content.
Hunt	1919	Flowers × white male	Productive; adherence; thin skin.
Irene	1919	Thomas × black male	Vigorous; adherence; large.
Lucida	1933	Irene × unknown male	Large; attractive appearance.
November	1919	Scuppernong × black male	Productive; good clusters; late.
Qualitas	1919	Thomas × black male	Good quality; sweet.
Spalding	1919	Flowers × white male	Good clusters; long season.
Stuckey	1919	Scuppernong × black male	Large; white; sweet.
Yuga	1934	San Monta × unknown male	Attractive; compact; thin skin.

[4] Alphonse Lavallee is grown commercially in California under the name Ribier.

Maryland

Grape-breeding work was started in 1912. The main attempts were to develop an early black grape of high quality. A study was made of the inheritance of fruit color. While an early black grape of quality for Maryland conditions was not obtained, a few seedlings were propagated in 1929 for further test, some of which show promise as desirable varieties.

Seedlings were grown of the following open-pollinated varieties: Bailey, Brilliant, Creveling, Goethe, Lindley, Lucile, Mericadel, Red Giant, Salem, Wilder, Woodruff, Worden, Wyoming. Seedlings were also obtained from the following crosses: Agawam × Clinton, Brighton × Winchell, Campbell × Winchell, Clinton × Black Hamburg, Delicious × Winchell, Diana × Clinton, Diamond × Clinton, Eclipse × Brilliant, Lindley × Clinton, Lindley × Campbell Early, Lindley × Winchell, Moore Early × Winchell, Salem × Clinton, Winchell × Brilliant, Winchell × Clinton, Winchell × Worden, Worden × Winchell, Worden × Clinton.

Minnesota

Grape breeding has been in progress since 1908. The early work stressed the use of Beta as a hardy parent in combination with the higher quality varieties, Agawam, Campbell, Concord, Delaware, Janesville, Jessica, Lutie, Salem, and Witt. In later work since 1923, selected seedlings from these crosses have been used in further breeding work by intercrossing, crossing with various dessert varieties, and inbreeding. Breeding studies have been conducted, principally with respect to winter hardiness. Selections have been made to develop homozygous material for genetic studies and for superior value in breeding work. Cytological studies have been made on pollen development with special reference to sterility. A chromosome number of 38 was determined in the Beta grape, using root-tip material in making the count determinations.

Missouri

Grape breeding has been in progress since 1933. Earlier crosses were made with the objective of better quality, improved vigor, and more resistance to disease. Seedlings have been obtained from the following grape crosses: Campbell Early × Eaton, Columbia × 42–18, Concord × Caco, Concord × Eaton, Concord × 42–18, Concord × Triumph, 42-2 × 42-8, 44–5 × Caco, 44–5 × Concord, Goethe × Concord, Goethe × 42–8, Herbert × Agawam, Herbert × Concord, Herbert × 42–8, Hubbard × Beta, Eclipse × Eaton, Eclipse × 42-8, Eclipse × Triumph, Lindley × Caco, Lindley × Concord, Lindley × 42-8, Lindley × 42–17, Lindley × Triumph, Moore Early × Caco, Moore Early × Concord, Muench × Beta, Muench × 42–17, Muench × Triumph, Triumph × Concord, Triumph × Eaton, Triumph × 42–17, Triumph × Portland.

In 1935 Concord and Moore Early were crossed with Lindley, Herbert, and Barry (Rogers hybrids) to develop self-fertile varieties with some of the desirable qualities of the Rogers hybrids.

New York

Grape-breeding work at Geneva was started in 1888. More than 30,000 grape seedlings have been grown at this station. Selfing and crossing have been used extensively. Of 282 selfed varieties and selfed seedlings, no seedling appeared worthy of commercial trial. Three hundred and twenty-five varieties and seedlings have been used in the breeding work. Particular attention has been given to vigor, hardiness, productiveness, disease resistance, and quality of fruit. In connection with the breeding work, a study has been made of the transmission of different characters. Reports have been made on the inheritance of stamen characters, color of fruit, and transmission of other vine and fruit qualities. Chromosome counts give a diploid number of 38 in the grape varieties and species studied, excepting several Gigas strains, which give a count of 76. Some seedlings with the triploid chromosome number have recently been produced.

In cooperation with the New York Botanical Garden, extensive breeding work has been carried on mainly for the production of seedless varieties suitable to eastern conditions. Reports have been issued covering this phase of the work. From 1907 to 1937, 21 varieties have been introduced as the result of breeding work conducted at Geneva and Fredonia, N. Y., and in cooperation with the New York Botanical Garden (table 4).

Table 4.—*Grape varieties introduced by the New York State Agricultural Experiment Station (Geneva and Fredonia)*

Variety	Year introduced	Parentage	Superior characters
Brocton	1919	Brighton × (Winchell × Diamond)	Productive: white; oval.
Bronx Seedless	1936	(Goff × Dina) × Sultanina	Productive; red.
Dunkirk	1920	Brighton × Jefferson	Medium productive; red.
Fredonia	1915	Champion × Lucile	Large cluster and berry.
Goff	1907	Goff seedling no. 19	Productive; reddish black.
Golden Muscat	1927	Muscat Hamburg × Diamond	Very productive; large cluster; white.
Hanover	1928	Brighton × Niagara	Productive: red.
Keuka	1923	Chasselas Rose × Mills	Productive; red; late.
Melton	1923	Triumph × ((Winchell × Diamond) × Jefferson).	Productive; white.
Ontario	1908	Winchell × Diamond	Productive; white; early.
Pontiac	1922	Herbert × Worden	Medium productive; black.
Portland	1912	Champion × Lutie	Productive; early; white.
Ripley	1912	Winchell × Diamond	Productive; white.
Seneca	1930	Lignan Blanc × Ontario	Medium productive; early; white.
Sheridan	1921	Herbert × Worden	Productive; black.
Stout Seedless	1930	(Triumph × Dutchess) × Sultanina Rosea.	Medium productive; white.
Urbana	1912	Ross × Mills	Medium productive; red; late.
Van Buren	1924	Fredonia × Worden	Earliness.
Watkins	1930	Mills × Ontario	Medium productive; nearly black.
Wayne	1927	Mills × Ontario	Productive; black.
Westfield	1922	Herbert × Concord Seedless	High sugar; high color.

From the following crosses at the New York (Geneva) station, 6 seedlings have been propagated for naming, 35 for extensive trial, and 69 for a small trial: Ontario × Sheridan, Sheridan × Ontario, Ontario × Gros Guillaume, Ontario × Black Corinth, Ontario × Hubbard, Ontario × Moore Early, Ontario × Muscat Hamburg, Eclipse × Portland, Iona × Ontario, Herbert × Watkins, Concord × Sta.[5] 10085 (Triumph × Mills), Sta. 10115 (Triumph × Mills) × Concord, Portland × Moore Early, Wayne × Iona, Hubbard × Gros Guillaume, Hubbard × Golden Muscat, Zinfandel × Ontario, Mead No. 9 × Noir Hatif de Marseille, Golden Muscat × Wayne, Golden Muscat × Sultanina, Sta. 10842 ((Herbert × Triumph) × (116 × Jefferson)) × Sultana, Sta. 7408 (Ross × Mills) × Moore Early, Sta. 8691 ((Iona × Vergennes) × Jefferson) × Khalili, Sta. 8691 (Iona × Vergennes) × Muscat Hamburg, Sta. 8717 (Kensington × Triumph) × Watkins, Sta. 9104 (Triumph × Iona) × Seneca, Sta. 9104 (Triumph × Iona) × Seneca, Sta. 10420 (Muscat Hamburg × Ripley) × Khalili, Sta. 10439 (Bakator × Diamond) × Seneca, Sta. 10526 (Muscat Hamburg × Ripley) × Melton, Sta. 10774 (Chasselas Besson × Diana) × ((Triumph × Sta. 116) × Jefferson) × Muscat Hamburg, Sta. 10605 (Frankenthal Precoce × Diamond) × Ontario, Sta. 10108 (Triumph × Mills) × Ontario, Sta. 10144 (Mills × Triumph) × Dunkirk, Sta. 8536 (Goff × Iona) × Ontario, Sta. 7408 (Ross × Mills) × Ontario, Sta. 10526 (Muscat Hamburg × Ripley) × Khalili. Principal grape varieties used in breeding work by the New York (State) Station:[6] Agawam, Barry, Berckmans, Brighton, Butler, Campbell, Catawba, Champion, *Chasselas Golden, Chasselas Rose, Clinton, Colerain, Collier, Concord, Concord Seedless, Cottage, Croton, Daisy, Delaware, Diamond, Diana, Dutchess, Eclipse, Franken Riesling, Fredonia, Goethe, Golden Muscat, *Herbert, Hubbard, Hubbard Seedless, *Iona, Jessica, Keuka, Lindley, Lucile, Manito, Massasoit, Melton, *Mills, Moore Early, *Muscat Hamburg, Noah, *Ontario, Panariti, Pekin, Petit Syrah, Portland, Regal, Ripley, Rosaki, Salem, Secretary, Seneca, Sheridan, Stout Seedless, Triumph, Urbana, Vergennes, Wayne, Winchell, Worden, and also station seedlings nos. 7408, 8536, 9130, and 10919.

Grape material available for breeding in addition to American Euvitis varieties includes early-maturing vinifera varieties and the following list of unusual varieties:

From Africa: Primativo, Roussanne.

French hybrids: Caperan, Commandant, Bertile, Seyve 2667, Cartier 1, Malegue 2049–3, Peage 5–10, Seibel 2, 14, 1000, 4629, 4643, 5136, 5296, 5437, 5455, 5760, 5898, 6339, 6905, Villard 2–108.

---

[5] "Sta." denotes station seedling.

[6] An asterisk (*) denotes varieties that have made good parents; others may appear later.

From Hungary: Königin Elizabeth, Königin der Weingarten, Malaga Bleu, Millenium Straube, Szauter Musk.

From Union of Soviet Socialist Republics: Albourla, Aneb-el-Cadi, Apapnish White, Buaki, Charas, Hisakasy, Maska, Muscat de Crime, Rish Baba, Rosy Taifi, Sabsa, Said Galumi, Shuvargani, Tabyrn, Ter-Gulmer, White Chilaki.

South Dakota

Many seedlings of the wild grape of the Dakotas were grown, but little variation and no apparent improvement over the wild type was noticed. This led to the crossing of the wild grape of the Dakotas with choice American-type grapes. The hardiness of the wild type, *Vitis vulpina*, appeared to be strongly dominant, and 32 varieties that appeared hardy and that have superior fruit qualities for the more northern regions were introduced in 1925.

Table 5 indicates the parentage and some of the superior qualities of grape varieties introduced by the South Dakota Station.

Table 5.—*Grape varieties introduced by the South Dakota Agricultural Experiment Station*

Variety	Parentage	Qualities
Arikara	Lady × North Dakota wild	White; productive, large
Atkan	do	White, sweet, long bunch.
Azita	Beta × North Dakota wild	Sweet; vigorous, medium size
Caddo	Beta × Agawam	Black; sweet, good flavor
Chonkee	Lady × North Dakota wild	White; productive, vigorous
Chontay	Massasoit × Beta	Black; vigorous; good flavor
Edapa	Merrimac × Beta	Black; large; good quality
Emana	Beta × Agawam	Black, large, good flavor
Eona	Lady Washington × Beta	White; productive; sweet
Lachala	Lady × North Dakota wild	White; productive, large
Luza	Merrimac × Beta	Red, sweet; meaty
Mandan	Wilder × North Dakota wild	Black, productive, early
Manota	Merrimac × Beta	Black; large; good quality
Napka	Salem × Beta	Black; vigorous, good flavor
Nompah	Lindley × South Dakota wild	Black, large, good flavor
Oglala	Merrimac × Beta	Black, productive; large
Onaka	Beta × Salem	White, productive, large
Osbu	Beta × Agawam	Black, medium size, good flavor.
Pontigo	Lady × North Dakota wild	Light red, very large sweet
Ree	do	White, productive late
Santee	Merrimac × Beta	Black, productive, large
Shakoka	Lady × North Dakota wild	Black, vigorous, large
Siposka	do	Black, large.
Sonona	do	Light red, productive, sweet
Tahama	do	Black; vigorous, large
Teopa	Lindley × South Dakota wild	White, sweet
Toscha	Lady × North Dakota wild	White, sweet, large.
Wachepa	Lady Washington × Beta	Do.
Wakpala	Merrimac × Beta	Black; very large, good flavor
Wecota	Lady Washington × Beta	White, sweet
Wetonka	Beta × Salem	Black, productive, vigorous
Yasota	Merrimac × Beta	Black, large, wild flavor

Texas

Grape-breeding work started in 1935. Seedlings of selfed and crossed varieties are being obtained in an attempt to improve fruiting varieties relative to vigor, adaptability, disease resistance, and fruit qualities. Breeding material includes vinifera and native varieties and native grape species. Seedlings have been obtained from the following selfed varieties: Allaga, Elvicand, Extra, Lomanto, Marguerite, Mathilda, and R. W. Munson.

Virginia

Grape-breeding work started in 1930 by raising seedlings of open-pollinated standard varieties. Varietal crosses of American native varieties were made in 1935. The main objective is to improve the flesh quality. A study is being made of pollen compatibility, fruit characters, and resistance to disease.

From open-pollinated blossoms seedlings have been grown from the following varieties: Catawba, Concord, Eumelan, Moore Early, Niagara, and Worden.

Seedlings are also being grown from the following controlled crosses: Agawam × Amber Queen, Agawam × Barry, Agawam × V. L. B., Amber Queen × Agawam,

Amber Queen × Catawba, Eumelan × Catawba, Eumelan × Delaware, Eumelan × Wilder, Eumelan × Worden, Eumelan × V. L. B., Niagara × Worden, Wilder × Amber Queen, and selfed seedlings of Agawam, Catawba, Delaware, and Regal.

Two seedlings of earlier crosses were introduced in 1936: V. L. B. (Campbell Early × Herbert) and Agel (Agawam × Regal).

United States Department of Agriculture

Grape-breeding work was started with vinifera varieties at Fresno, Calif., in 1923, to produce seedless varieties suitable for table and raisin use, quality table varieties, and juice varieties Crosses have been made between many vinifera varieties, using the seedless varieties as the male parents. Large-berry varieties have been used to increase size, and highly flavored varieties to improve quality. Seedlings of standard varieties, selfed seedlings, and backcrosses are being grown to study genetic characters and the possibility of obtaining desirable qualities. Some cytological work has been done on pollen development and the development of the ovule. Studies have been made on the inheritance of vine, flower, and fruit characters.

Seedlings are being grown of phylloxera-resistant stock varieties and crosses of stock varieties for further studies on rootstocks resistant to root knot nematode. Varietal improvement through the selection of bud sports is in progress. Publications have been issued on the progress of the breeding work and the production of seedless varieties. Grape-breeding material includes 338 American native varieties, 95 Franco-American direct producers, 136 phylloxera-resistant rootstocks, over 550 varieties of *Vitis vinifera*, and in addition over 200 more recent Plant Introduction numbers from foreign sources.

Seedlings of the following crosses have been obtained: Alexandria × Alicante Bouschet, Alexandria × Monukka, Alexandria × Calmette, Alexandria × Corinthe Blanc, Alexandria × Corinthe Rose, Alexandria × Damas Rose, Alexandria × Hunisa, Alexandria × Malaga, Alexandria × Panariti, Alexandria × Sultanina, Alexandria × Sultanina Gigas, Alexandria × Sultanina Rosea, Emperor × Monukka, Emperor × Maraville de Malaga, Emperor × Sultanina, Flame Tokay × Monukka, Flame Tokay × Maraville de Malaga, Flame Tokay × Sultanina, Gros Guillaume × Monukka, Gros Guillaume × Maskah, Gros Guillaume × Sultanina Gigas, Malaga × Monukka, Malaga × Sultanina, Maraville de Malaga × Monukka, Maraville de Malaga × Sultanina, Maraville de Malaga × Sultanina Gigas, Maraville de Malaga × Tagonti Rouge, Maskah × Gros Guillaume, Muscat Hamburg × Monukka, Muscat Hamburg × Panariti, Ohanez × Monukka, Panariti (sport) × Monukka, Pizzutella × Monukka, Rodites × Monukka, Rodites × Gros Guillaume, Vigne de Zericho × Rodites.

Seedlings have been obtained from crosses of station seedlings and standard varieties as follows: (Alexandria × Monukka) 9642 × Monukka, (Alexandria × Monukka) 96419 × Monukka, (Alexandria × Corinthe Rose) 105616 × Monukka, (Alexandria × Corinthe Rose) 105713 × Monukka, (Alexandria × Sultanina) 96212 × Sultanina, (Damas Rose × Monukka) 8635 × Monukka, (Damas Rose × Monukka) 86310 × Monukka, (Damas Rose × Monukka) 8649 × Sultanina Gigas, (Damas Rose × Monukka) 86311 × Sultanina Gigas, (Muscat Hamburg × Monukka) 106212 × Monukka, (Muscat Hamburg × Monukka) 106312 × Monukka, (Pizzutella × Monukka) 10644 × Monukka, (Pizzutella × Monukka) 10649 × Monukka, and Muscat Hamburg × (Alexandria × Sultanina Rosea) 96212.

Seedlings of the following selfed varieties are being grown: Agadia, Alexandria, Carignane, Chasselas Cioutat, Chasselas Doré, Chasselas Rose de Falloux, Cinsaut, Crabbs Burgundy, Emperor, Flame Tokay, Foster, Gros Guillaume, Lenoir, Malaga, Maraville de Malaga, Maskah, Mission, Muscat Hamburg, Mondeuse, Panariti, Palomino, Petit Syrah, Prune de Cazouls, Sauvignon Vert, Semillon, Sylvaner, Traminer, Zeinc, Zinfandel, and seedlings of the following Plant Introduction nos. 105074 to 107086, inclusive, 105922, and 107007.

Seedlings of the following selfed station seedlings are being grown: (Alexandria × Alicante Bouschet) 9582, (Alexandria × Alicante Bouschet) 95915, (Alexandria × Alicante Bouschet) 95919, (Alexandria × Monukka) 9623, (Alexandria × Monukka) 9627, (Alexandria × Monukka) 9628, (Alexandria × Monukka) 96311, (Alexandria × Monukka) 96317, (Alexandria × Monukka) 96319, (Alexandria × Monukka) 9642, (Alexandria × Monukka) 9646, (Alexandria × Monukka) 96419, (Alexandria × Calmette) 96017, (Alexandria × Corinthe Rose) 105616, (Alexandria × Malaga) 9571, (Alexandria × Malaga)

95818, (Alexandria × Malaga) 10587, (Alexandria × Malaga) 105915, (Alexandria × Panariti) 9603, (Alexandria × Panariti) 9118, (Alexandria × Sultanina) 96212, (Alexandria × Sultanina Rosea) 9612, (Alexandria × Sultanina Rosea) 96216, (Muscat Hamburg × Monukka) 106211, (Muscat Hamburg × Monukka) 106212, (Muscat Hamburg × Monukka) 10633, (Muscat Hamburg × Monukka) 10637, (Muscat Hamburg × Monukka) 106312, (Muscat Hamburg × Monukka) 106316, (Muscat Hamburg × Panariti) 8621, (Muscat Hamburg × Panariti) 8623, (Olivette Blanche × Muscat Hamburg) 10616, (Olivette Blanche × Muscat Hamburg) 10626, (Olivette Blanche × Olivette Noire) 9563, (Olivette Blanche × Olivette Noire) 9564, (Olivette Blanche × Olivette Noire) 9566, (Olivette Blanche × Olivette Noire) 9572, (Pizzutella × Monukka) 10649.

Seedlings of Vinifera grape crosses that have fruited at the Fresno station of the United States Department of Agriculture

Parentage	Superior qualities obtained
Alexandria × Alicante Bouschet	Productive; vigorous; red juice; rich flavor.
Alexandria × Monukka	Productive; vigorous; seedless; muscat flavor; adherence.
Alexandria × Calmette	Productive; red juice; rich flavor.
Alexandria × White Corinth	Productive; all white fruit.
Alexandria × Corinthe Rose	Productive; some red fruit; rich flavor.
Alexandria × Damas Rose	Productive; large-size berry.
Alexandria × Hunisa	Vigorous.
Alexandria × Malaga	Productive; large-size cluster and berry; rich flavor.
Alexandria × Panariti	Productive; none seedless.
Alexandria × Sultanina	Productive; vigorous; seedless; no muscat flavor.
Alexandria × Sultanina Rosea	Productive; vigorous.
Damas Rose × Monukka	Productive; vigorous; large size; some seedless.
Gros Guillaume × Monukka	Adherence; large size; seedless.
Muscat Hamburg × Monukka	Productive; muscat flavor; some seedless.
Muscat Hamburg × Panariti	Productive; small size; none seedless.
Ohanez × Monukka	Seedless; late ripening.
Olivette Blanche × Muscat Hamburg	Elongated types; muscat flavor.
Olivette Blanche × Olivette Noire	Elongated types; white, red, and black colored fruit.
Pizzutella × Monukka	Elongated fruit types; seedless; early ripening.
Rodites × Monukka	Late ripening; seedless.
Rodites × Gros Guillaume	Late ripening; firmness of fruit.

Grape-breeding work with native American grapes and *Vitis vinifera* has been in progress at Arlington, Va., and Beltsville, Md., since 1933, to originate seedless varieties and to improve the quality and adaptability of native American varieties especially for central and southern regions.

Seedlings of the following varieties are under observation at the Beltsville station: August Giant, Bailey, Black Eagle, Caco, Captain, Captivator, Ellen Scott, Eumelan, Golden Muscat, Goff, Manito, Mills, Nitodal, Norwood, Oriental, Rogers nos. 13, 32, 33, Urbana.

Seedlings have been obtained of the following native bunch grape crosses: Bailey × Brilliant Seedling, Captivator × Beacon, Captivator × Columbian Imperial, Captivator × Fredonia, Champanel × Manito, Champanel × Niagara, Columbian Imperial × Empire State, Delaware × Goethe, Empire State × Manito, Goethe × Delaware, Lenoir × Salem, Loretto × Oriental, Manito × Caco, Manito × Empire State, Oriental × Portland, Rogers 13 × Beta.

Seedlings have been obtained of the following native American bunch grapes and vinifera crosses: Atoka × Gros Guillaume, Bailey × Foster, Bailey × Goolabie, Bailey × Gros Guillaume, Blauer Portugieser × Monukka, Campbell Early × Monukka, Campbell Early × Alphonse Lavallee (Ribier [7]), Captain × Goolabie, Captivator × Monukka, Captivator × Alphonse Lavallee, Catawba × Monukka, Catawba × Muscat Hamburg, Catawba × Alphonse Lavallee, Catawba × Sultanina, Cloeta × Goolabie, Cloeta × Muscat Hamburg, Columbian Imperial × Monukka, Columbian Imperial × Goolabie, Concord × Monuk-

[7] See footnote 4, p. 656.

ka, Concord × Sultanina, Ellen Scott × Sultanina, Lucile × Monukka, Manito × Chasselas de Fontainebeau, Manito × Alphonse Lavallee, Niagara × Sultanina, Ontario × Blauer Portugieser, Oriental × Albardiens, Oriental × Monukka, Oriental × Goolabie, Oriental × Muscat Hamburg, Oriental × Panariti Oriental × Sultanina, Portland × Blauer Portugieser, Triumph × Monukka, Vergennes × Monukka, Vergennes × Alphonse Lavallee.

Muscadine grape-breeding work of the Department has been centered at the North Carolina State Department of Agriculture Test Farm, Willard, N. C. This work was started in 1907. From two early crosses, two perfect-flowered hermaphrodite seedlings were obtained. By selfing one of these plants, and also by using the pollen from this type to pollinate standard muscadine varieties, an additional number of perfect-flowered seedlings were obtained. Better berry adherence, increased productivity, and improved fruit quality have been reported. True hybrids were obtained between *Vitis rotundifolia* and *V. vinifera*, and also between *V. rotundifolia* and varieties of American bunch-type grapes.

The following hybrid seedlings of *Vitis rotundifolia* and varieties of American bunch-type grapes obtained at Willard, have been selected for further study: James × Winchell, Labama × Brilliant, muscadine seedling × Campbell Early, muscadine seedling × Catawba, muscadine seedling × Delaware, muscadine seedling × Goethe, muscadine seedling × Winchell, Scuppernong × Louisiana, San Jacinto × Ives, Thomas × Concord, Thomas × Goethe.

The following hybrid seedlings of *Vitis rotundifolia* and *V. vinifera* have been selected for further study: George × Goolabie, muscadine seedling × Black Morocco, muscadine seedling × Semillon, San Alba × Malaga, San Alba × Semillon, San Jacinto × Malaga, Thomas × Black Morocco, Thomas × Maraville de Malaga.

Muscadine seedlings selected for further trial are the following: 10- Latham × (Eden × (Eden × male Munsoniana)), 14- Latham × (Thomas × (Eden × (Eden × male Munsoniana))), 3- Latham × male (muscadine seedling × (Eden × (Eden × male Munsoniana))), 1- Latham × male (muscadine seedling × (Eden × male Munsoniana)), 8- Luola × (Eden × (Eden × (Eden × male Munsoniana))), 3- Luola × (Thomas × (Eden × (Eden × male Munsoniana))), 5- Luola × (muscadine seedling × (Eden × (Eden × male Munsoniana))), 1- Luola × (muscadine seedling × (Eden × (Eden × male Munsoniana))), 1- San Alba × (Eden × (Eden × male Munsoniana)), 2- San Alba × male (Eden × (Eden × male Munsoniana)), 6- San Alba × (Thomas × (Eden × (Eden × male Munsoniana))), 3- San Alba × (muscadine seedling × (Eden × male Munsoniana)), 5- San Rubra × male (Eden × (Eden × male Munsoniana)), 3- San Rubra × (Eden × (Eden × male Munsoniana), 1- San Rubra × (Thomas × (Eden × (Eden × male Munsoniana))), 1- muscadine seedling × (Eden × (Eden × male Munsoniana)), 1- muscadine seedling × male (Eden × male Munsoniana), 1- muscadine seedling × (muscadine seedling × (Eden × (Eden × male Munsoniana))), 13- muscadine seedling × male (Eden × (Eden × male Munsoniana)), 1- muscadine seedling × (Eden × (Eden × male Munsoniana)), 2- muscadine seedling × (muscadine seedling × (Eden × (Eden × male Munsoniana))), 20- muscadine seedling × (muscadine seedling × (Eden × (Eden × male Munsoniana))), 3- muscadine seedling × (Eden × male Munsoniana), 1- (Eden × (Eden × male Munsoniana)) × male (Eden × (Eden × male Munsoniana)), 3- (James × white male) × (Eden × (Eden × male Munsoniana)), 2- (James × white male) × (muscadine seedling × (Eden × (Eden × male Munsoniana))), 1- James seedling × (muscadine seedling × (Eden × (Eden × male Munsoniana))), 1- muscadine seedling × male (Eden × (Eden × male Munsoniana)), 1- selfed seedling (James × (Eden × (Eden × male Munsoniana))), 3- selfed seedlings (Thomas × (Eden × (Eden × male Munsoniana))), 1- selfed seedling (muscadine seedling × (Eden × (Eden × male Munsoniana))), 2- selfed seedlings (muscadine seedling × (Eden × (Eden × male Munsoniana))). (All pollen parents were hermaphrodite seedlings unless designated as male.)

Vinifera grape varieties available for breeding work in United States Department of Agriculture experiment vineyards [8]

[Alphabetically arranged]

Ach-I-Soum, Affenthaler, Agadia, Agra Ash, Ak Saibe, Aibatly Isium, Ajmi, Ak-usum, Aldara, Aleatico, Alexandria, Alicante, Alicante Bouschet, Alnwick

[8] This list contains many names of Persian or other foreign origin that have no exact English equivalent and also includes some recent introductions that have not yet found a place in American grape literature. Such names are to be regarded as tentative and not necessarily authentic and final.

seedling, Alvarna, Amlachu, Aneb-el-Cadi, Angur Khalili, Angur Noir Grande, Apapnish White, Appley Towers, Aramon, Ascot Citronelle, Askaree, Asmi, Aspiran Noir, Atch Gau, Augulato, Awasarghua.

Baba, Bakator, Barbarossa, Barbera, Barducci, Bastardo, Beclan, Bellino, Bengi, Bermestia Violacea, Bicane, Black Alicante, Black Hamburg, Black Morocco, Black Prince, Black Seedless, Black Shahanee, Black Zante (South Africa currant grape), Blanc d'Ambre, Blaney White, Blauer Portugieser, Boal de Madeira, Bocalilla, Bolgnino, Bonarda, Boudelais, Bowood Muscat, Brustiano, Buaki, Buccleuch, Buckland Sweetwater, Buhirzi, Burger.

IMPROVEMENT OF STONE FRUITS

F. P. CULLINAN, Senior Pomologist, Division of Fruit and Vegetable Crops and Diseases, Bureau of Plant Industry[1]

THE beautiful and delicious varieties of peaches, plums, cherries, and apricots that make up the group of stone fruits as we know them today are undoubtedly vastly different from their early progenitors. Down through the centuries many wild species and varieties have been selected by man in his search for new food supplies and a better diet. Just how long this slow process of improvement of the various kinds of wild fruit has been going on, history does not relate. As civilization progressed we know that many of these wild fruits were taken from their native homes and distributed to new locations where there were new soils and new climatic conditions. In these new environments certain modifications occurred in size of tree and in size, shape, color, and flavor of fruit. Many trees perished in the new environments. Perhaps only a few survived the vicissitudes of climate in some of the regions into which they were taken. Through these early chance selections, however, a beginning was made in the improvement of the stone fruits.

Stone fruits are now grown in all parts of the Temperate Zone in the Northern Hemisphere. In the United States the culture, production, and sale of these fruits constitute a great industry. In 1931, the peak year of peach production, the commercial crop was over 76½ million bushels. According to the census of 1935, the country produced in the previous year about 45 million bushels of peaches, over 23 million bushels of plums, and 5 million bushels of cherries. Peaches, plums, and apricots in the fresh, canned, and dried state are consumed in large quantities in this country and abroad. About 200,000 tons of peaches are dried in the United States annually. California alone produces about 75 percent of the world output of dried prunes. Cherries are commercially important as fresh, canned, and frozen products. There is little wonder that such a great industry should demonstrate weaknesses in many of our long-cherished varieties of home-grown fruits. We might imagine that after all these years of selection and discovery of new sorts, we would have reached perfection. Unfortunately, this is not the case; in fact, it may be said that

[1] The author wishes to acknowledge his indebtedness to the following workers engaged in stone-fruit breeding in this country and abroad for their kind cooperation in furnishing information on the work in progress in their respective States and in furnishing lists of varietal and species material available for breeding studies: W. A. Alderman, Minnesota; J. S. Bailey, Massachusetts; M. A. Blake, New Jersey; M. J. Dorsey, Illinois; N. E. Hansen, South Dakota; F. W. HofMann, Virginia; Stanley Johnston, Michigan; T. J. Maney, Iowa; W. P. Tufts, G. L. Philp, E. C. Hughes, and J. W. Lesley, California; Richard Wellington, New York; S. H. Yarnell, Texas; A. F. Yeager, North Dakota; W. F. Wight, U. S. Bureau of Plant Industry, Palo Alto, Calif.; W. P. Baird, U. S. Northern Great Plains Field Station, Mandan, N. Dak.; E. F. Palmer and G. H. Dickson, Vineland, Ontario, Canada; H. Wenholz, New South Wales Department of Agriculture; and M. Ch. Miedzyrzecki, Ain Taoujdat, Morocco.

the work of improvement has just begun. We must continue the search for superior fruits, locating and studying the best raw materials, and then using the methods available to the plant breeder to combine desirable characters in a superior progeny.

BOTANY OF THE STONE FRUITS

Before attempting to consider the progress made in improving the varieties of stone fruits, a few words should be said about the botany of these fruits in general.

Botanists have classified the stone fruits into several species. While there has not been entire agreement as to the number of these species, most botanists place them in the great genus *Prunus* in the rose family (Rosaceae); others, however, separate the peach and its close relatives as the genus *Amygdalus*. The fruit develops from a one-celled ovary the wall of which ripens with a fleshy, juicy exterior, making up the edible part of the fruit, and a hard interior, called the stone or pit. The seed is contained in the stony portion.

But while these fruits have enough in common to be grouped in the same genus, they are quite different in many fruit, flower, and tree characters. When the fruits are ripe the flesh of some varieties parts readily from the pit. Such fruits are spoken of as freestones. Other varieties and species, for example, the canning cling type of peaches, are clingstones; that is, the flesh adheres to the stone. The individual fruits may be smooth, as in the apricot, nectarine, plum, and cherry, or hairy, as in the peach. They vary in size, color, and shape

THE *kind of search in which the breeder of peaches is engaged may be illustrated by the Elberta. This is the leading commercial peach in the United States today. It originated in Marshallville, Ga., in 1870, and in the 67 years since that time no better peach has been found, when all characteristics are considered. Yet in quality the Elberta does not rank as high as some other peaches, and the tree and the blossom buds are not sufficiently resistant to low winter temperatures. By suitable crosses, varieties have been developed that have better quality and more cold resistance in the bud; but these in turn are not adapted to so many different growing regions as the Elberta. Again, seedlings of Elberta have been found that ripen earlier than the parent variety and are better in quality and more attractive. It would seem possible, then, to develop a variety that would be a distinct improvement over Elberta, yet possess the valuable characteristics that have given the Elberta preeminence. Such an achievement would be a major contribution to fruit culture in the United States.*

with varieties and species. The flesh may be yellow, green, white, or red, or show various combinations of these colors. The stones or pits of the peach are rough and grooved, those of the plum and cherry relatively smooth, those of the apricot somewhat intermediate.

The flowers of the different stone fruits are quite characteristic for the respective groups. In the peach and the apricot they are borne singly, arising from one to three separate buds at a node. They are practically without stems in the peach, and nearly so in the apricot. They are on long stems in the cherry and on only moderately long ones in the plum, but in both these fruits the flowers are borne in clusters. The flowers of the edible plums are white or nearly so, while those of the peach and the apricot may be white, pink, or reddish.

As will be pointed out later, hybridization between some of the species of stone fruits is practically impossible.

METHODS OF BREEDING

The technique of stone-fruit breeding is not greatly different from that employed with other deciduous fruits. The essential operations are (1) collecting pollen to be used in the crosses, (2) emasculation of the flowers, (3) pollination, or the actual transfer of pollen to the stigmas of the pistil, (4) bagging, or protecting flowers from foreign pollen, (5) protecting fruit that has set, and (6) growing the seedlings for testing and study of the progeny.

Much of the breeding work with stone fruits is carried on with trees growing in the orchard. This has its drawbacks as well as many advantages. Blossom buds, flowers, or young developing fruits may be killed by cold. Under such conditions the continuity of breeding work is interrupted and a year's time is frequently lost. To avoid this difficulty, particularly in the regions of unfavorable climate, it has been found satisfactory to grow the trees in tubs or pots in the greenhouse. Emasculation and pollination can thus be carried on under controlled temperature. Since it is necessary for most stone fruits to have sufficient cold to bring them out of the rest period, the trees in tubs must be removed from the greenhouse in late summer or fall and placed out of doors or in a cool storage place. They may be brought back to the warm greenhouse by the middle of January, and the trees should then bloom in 3 or 4 weeks. While greenhouse trees do not reach the large size of those growing in the field and consequently do not produce as many blossoms, sufficient material can usually be obtained for certain crosses and for genetic and cytological study. In some cases it may be the only way blossoms can be produced for breeding work.

In obtaining pollen to be used in breeding it is usually necessary to collect shoots of the male parents desired and force the blossoms in a greenhouse or warm room in order to have the pollen available when the flowers on the tree are ready for pollination. Care should be taken, of course, that no foreign pollen is introduced by bees or other insects. When the flowers have opened, the anthers may be plucked off by running the filaments through a comb or some similar instrument that will lift off the anthers, which may then be placed in suitable containers to dry at room temperature of 65° to 70° F. When dry they break open and the pollen can be easily crushed out. The pollen

should be stored in a dry, cool place in vials or small boxes, from which it may be used directly when the crosses are made. It is convenient to leave a small camel's-hair brush in each container to use in the transfer of pollen.

The structure of the flowers of the peach and other stone fruits permits rapid emasculation. The stamens and the single pistil are enclosed under the folded petals. As the blossom expands from the bud scales, the calyx pushes up, carrying the nonexpanded leafy floral structures, forming a cup around the ovary. The long style of the pistil grows up through the stamens and under certain conditions may even push through between the petals before they expand (fig. 1). In the technique of emasculating, the calyx cup is easily cut with the nails of the thumb and first finger, and the entire corolla with its three rows of stamens attached may be lifted from the flower, leaving the pistil undisturbed. Early workers used sharp-pointed tweezers or scissors to cut the calyx cup, but the fingernail method is more rapid. With varieties of peach that are pollen-sterile, or varieties of plums and cherries that are self-unfruitful, emasculation is unnecessary in ordinary hybridization. A small percentage (0.5–0.8) of set is sometimes obtained in selfing self-unfruitful varieties. While this is a negligible amount in variety breeding, it should not be overlooked in cytological studies.

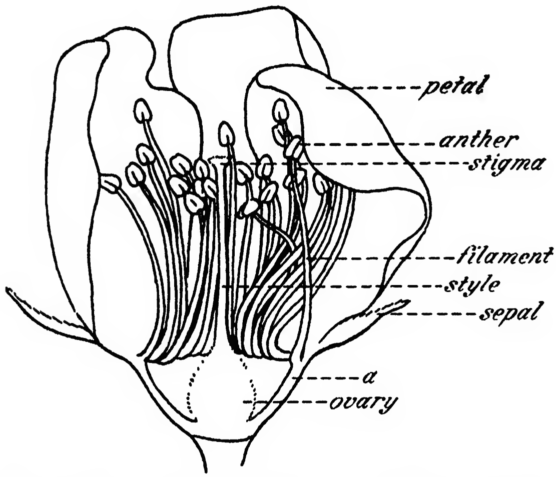

Figure 1.—Section through a peach flower showing arrangement of floral parts. By pinching through the calyx cup at *a* with the thumb and first finger, sepals, petals, and stamens are all removed in one operation, leaving the single pistil.

If emasculation is done just before the petals open (fig. 2)—which is just before any pollen that might cause selfing has been shed—the pollen of the parent to be used in the cross may be applied to the stigmas at once. Where a large number of pollinations are made on a single tree, it is frequently convenient to emasculate all the blossoms before pollinating. With the aid of the camel's-hair brush, from the pollen container a large number of flowers can be pollinated in a short time. Some workers prefer to use the tip of the finger, to which the pollen will adhere, and apply the pollen by touching the stigmas. Care should be taken to remove all pollen grains of one variety or strain from the finger before dipping into a container of another variety. The individual blossoms, single shoots, or entire branches that have been pollinated with a single pollen variety should be carefully labeled with full data on a tag or label that will remain until the fruit is harvested.

Figure 2.—Flower buds of peach (left) showing ideal stage for emasculation. Within 24 hours with temperatures of 70° to 75° F. the flowers will open as shown on right.

Protecting flowers after pollination is important. The method generally used is to tie a glassine or paper bag over the end of the branch bearing the pollinated flowers (fig. 3). Sometimes two or three flowers may be enclosed in a single bag. With some of the stone

fruits, particularly the peach, this method has not been entirely satisfactory, especially where the breeding work is done in the orchard. The relatively long style or stalk of the pistil is easily broken if the bag blows against it (fig. 4) causing loss in bagged flowers. It is necessary, however, to use some method of protection where only a

Figure 3.—When only a few blossoms on the tree are to be pollinated it is necessary to protect the flower from foreign pollen. A heavy paper bag or some cover not easily collapsed by the weather is necessary to prevent injury to the pistil.

few flowers on a tree are pollinated. A very heavy grade of paper bag with sufficiently sturdy basal folds to hold the sides out from the flower when the bag is inverted over the branch and tied is desirable to reduce the injury to a minimum. When large numbers of crosses are made, and when no special genetic or cytological studies are undertaken, it is doubtful whether peach flowers need to be protected, particularly if an entire branch or tree has been emasculated. Bees or other insects in visiting the emasculated flowers rarely touch the

stigmas and thus do not introduce foreign pollen. If an entire tree is emasculated for a large number of crosses, a tent built over the tree will prove satisfactory not only as a means of protection for the emasculated flowers but for insuring a large set of fruit under unfavorable weather conditions.

After fertilization of the ovules has taken place (fig. 5) and the style begins to darken and wither, the protecting paper bag is removed and an open-mesh bag of coarse cheesecloth or heavy net is placed over the end of the branch to protect the developing fruit. If the fruit drops off at maturity it will be held in the bag. Where the entire tree has been emasculated and tented, or where a number of branches on the tree have been pollinated without bagging, it is necessary to harvest the fruits before they fall.

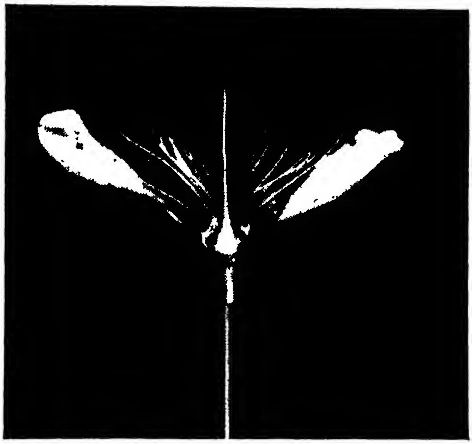

Figure 4.—A peach flower after fertilization, showing the pistil with its long style and the enlarging hairy basal portion, the ovary, which becomes the fruit. In the cherry, plum, apricot, and nectarine the fruit develops similarly from a single hairless ovary.

The stones are removed from the harvested fruit and are allowed to dry in a place free from molds and fungus contamination. Seeds of stone fruits require an after-ripening period of 2 to 3 months at low temperatures before they will grow. They are usually soaked for several hours and then placed in moist sand out of doors during the winter, or, preferably, they may be held for 2 or 3 months in a refrigerator or cold storage at about 40° F.

To insure a high percentage of seedlings in the case of valuable material, the best method is to remove the pits from the cold box, crack them, and remove the seeds. The seed coats are then removed and the young embryos sterilized in hypochlorite solution or some similar disinfectant and placed in small bottles on sterile nutrient agar to grow. When the young seedlings are rooted and a few inches tall, they may be transplanted from the culture bottles to pots in the greenhouse and later removed to the field or nursery row. The more common method of growing the seed is not to remove the seed coat but to plant the seed directly in pots in the greenhouse or in the nursery. Sometimes the pits are not cracked but are planted directly in the field in the fall when out-of-door temperatures will bring about the proper chilling required to insure growth of the seeds in the spring.

A great obstacle in stone-fruit breeding is the difficulty in getting the seeds of some crosses to resume growth. Many hundreds of seeds of crosses of sweet cherry, early-ripening varieties of peach, and other stone fruits have been planted, but no seedlings grew from apparently normal seeds. It is believed that planting the seeds on sterile nutrient

agar will be helpful. At the present time, however, there are stubborn seeds of early-ripening varieties of peach and cherry that will not grow even though given the agar-culture treatment. Many such varieties possess desirable characteristics, but they cannot be used as female parents until some method is found to obtain germination of the apparently normal seed they produce.

To economize space the young seedlings are usually planted in test blocks in rows 10 feet apart, with the trees 5 feet apart in the row, which is about as close as cultural operations will permit. At least

Figure 5.—**Peach flowers after emasculation and fertilization. The single pistil (*A*) is normal, but occasionally, in some varieties and under certain nutritional conditions, two (*B*) or more pistils (*C*) may develop in a single flower.**

3 or possibly 4 years must elapse before fruit characters can be studied. If it is decided to hasten the fruiting of the progeny, buds or scions can be taken from the seedlings when they are large enough and grafted into branches of bearing trees. In general, budding has proved a more satisfactory method for top-working peach than grafting. In California, however, grafting has proved very satisfactory in the hands of experienced men when dormant scions were placed early in the spring in the cut-back branches of trees 4 to 8 years old. Fruit may be obtained in 2 years from budding, and sometimes in 1 year from grafts. Where tree characters of the seedlings are to be studied, this information is best obtained by leaving them in the field for some years after first fruiting.

Under the most favorable conditions it requires about 5 years from the time the cross is made until a preliminary reading is obtained from the seedling and trees can be propagated for testing in the orchard. If we assume the average life of a peach tree to be about 15 years, then it will be about 20 years before full evaluation can be made of the lifetime merits of a variety. Frequently a much longer time elapses before the value is determined, because of the fact that new varieties are not tested promptly under widely varying soil and climatic conditions.

PEACHES

Early History

The original home of the peach (*Amygdalus persica* L. or *Prunus persica* Batsch.) was thought to be Persia, since this fruit was doubtless introduced into Greece from that country shortly after the beginning of the Christian Era. De Candolle concludes, however, that the peach has never been truly wild in Persia. Botanists agree that the peach is wild in China. The late Frank N. Meyer, explorer of the United States Department of Agriculture, reported finding many wild peaches in China, the fruits of which are inedible, being small and hairy, hard, and with a sourish flesh (*17*).[2] The peach has also long been cultivated in China. It was written about some 2,000 years before its introduction to the Roman world. Reference to the "tao", meaning peach, has been found in the writings of Confucius in the fifth century B. C. and in the Ritual in the tenth century B. C.

There is evidence that the peach reached France and possibly Spain at about the time it was introduced into Greece. From southern Europe it spread to northern Europe, possibly the greatest spread taking place from France. In more recent times France has been an important nursery center, and in the fifteenth and sixteenth centuries nursery trees were sent from France and disseminated through England, Belgium, the Netherlands, and Germany.

Few other fruits are grown under such varied conditions and over such extended areas as the peach. Once a wild inhabitant of China, it is now cultivated in every part of that vast country. Extensive plantings of the peach occur in Turkistan and Persia. It is not surprising, therefore, that early writers regarded Persia as the original home of the peach, as is suggested by the species name *persica* later given it. Peaches thrive in all parts of southern Europe and are grown in sheltered places in the northern latitudes. In the United States the peach found such congenial surroundings that it spread rapidly and widely, leading botanists three centuries later to believe it was native to this country. Today peach varieties are found growing in practically every State of the Union. While the fruit is not grown commercially in regions that are subject to low winter temperatures, some varieties or seedlings are able to withstand the winter temperatures in the colder parts of the country.

Because of the general distribution of the peach in Europe, Asia, South Africa, Australia, South America, and the United States, there has been a general selection of varieties best adapted to the various regions and climatic conditions, as well as to the preferences of consumers. Through this process of selection and hybridization peach varieties with widely differing characteristics have been developed and propagated. Some of the wide differences are so marked that botanists have been inclined to separate the peach into races and, in a few instances, species.

American pomologists (*25*) in the past century tried to divide peaches into four groups or races: (1) The Persian race, brought to North America by the early settlers, best represented by varieties

[2] Italic numbers in parentheses refer to Literature Cited, p. 746.

of the Crawford group; (2) the north China or Chinese Cling race, characterized by large fruits with tender skin and flesh, vigorous tree growth, and abundant and regular bearing, and including such Chinese varieties as Chinese Cling, Chinese Free, and later descendants Belle and Elberta; (3) the south China race, sometimes called

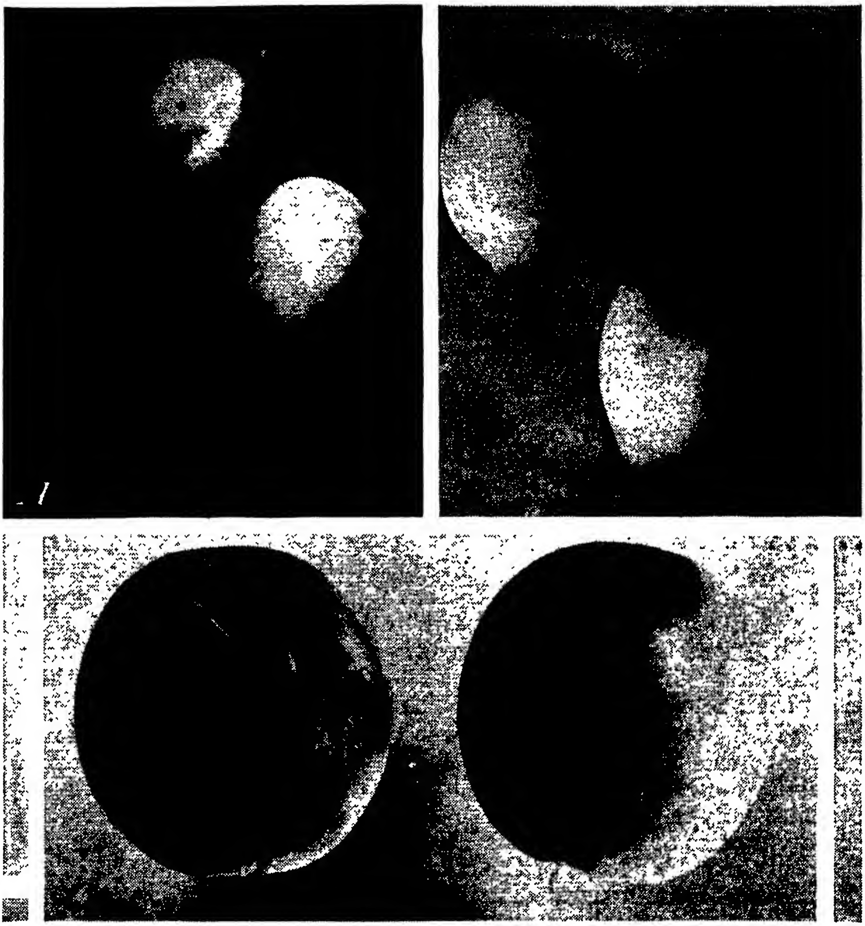

Figure 6.—Shapes of different types of peaches that may be used in breeding: *A*, Peento, or so-called saucer peach of the Gulf States; *B*, the honey peach of Florida and Texas, represented by varieties such as Imperial and Honey; *C*, peach of the Chinese Cling type, representing most of our present-day commercial freestone and canning cling varieties.

the Honey, represented by varieties that bear small, oval to pointed, white-fleshed fruits with a peculiar honey-sweet flavor, and adapted in the United States only to some subtropical sections; (4) the Peento race, a warm-climate type with trees inclined to be evergreen and to bear fruits that are much flattened endwise, white-skinned and white-fleshed, and sweet to very sweet. However, all varieties hybridize

freely, and there has been so much crossing between the groups that it is practically impossible to classify many of our present yellow- and white-fleshed varieties on this basis (*16*) (fig. 6).

The nectarine was formerly thought to be a different species from the peach. It is now known that the nectarine is simply a smooth-

Figure 7.—The beginning of commercial peach growing. The early settlers planted fruit trees near the homestead. The home orchard frequently gave place to large commercial plantings.

skin peach. The trees differ in no respect from the peach, and it is impossible to tell a peach tree from a nectarine tree. The leaves are the same. The fruits and seeds have essential characteristics in common. In short, the only difference between the peach and the nectarine is the absence of hairs in the latter. Nectarines are known to have come from peach seeds, and vice versa.

Commercial Peach Growing and Its Stimulus to Variety Improvement

Commercial peach growing in the United States began early in the nineteenth century (fig. 7). Large orchards were planted in Maryland, Delaware, and New Jersey. Prior to this time thousands of peach trees, all seedlings, were planted by growers. Many of the varieties grown in those early years were apparently better suited for making brandy than for general consumption as canned or fresh fruit. While the art of budding and grafting had been known for a long time, it was not until early in the nineteenth century that large commercial orchards of varieties propagated from clons were used.

TABLE 1.—*Fifty varieties of peach grown commercially in the United States during the past 25 years*

Variety	Place of origin	Date of origin	Originator or introducer	Color of flesh	Firmness of flesh [1]	Stone free or cling	Ripening date [2]	Quality
Admiral Dewey	Vineyard, Ga	1899	J D Husted	Yellow	Soft melting	Semifree	July 15–23	Good
Alton	Denison, Tex	1899	T V Munson	White	do	do	Aug 3–10	Do
Arp	Arp, Tex	1897	C P Orr	Yellow	do	Semicling	Early	Very good
Belle	Marshallville Ga	18[illegible]0	L A Rumph	White	Melting	Free	Aug 16–20	Good
Brackett	Augusta, Ga	1912	J P Berckmans	Yellow	do	do	Aug 29–Sept 1	Do
Carman	Mexia, Tex	1889	J W Steubenrauch	White	Soft melting	Semifree	July 31–Aug 5	Do
Chairs	Anne Arundel County Md	1880	Franklin Chairs	Yellow	Melting	Free	Late midseason	Excellent
Champion	Nokomis Ill	1880	I G Hubbard	White	Soft melting	do	Aug 17–22	Do
Chili	Chili N Y	1845 (?)	Pitman Wilcox	Yellow	Melting	do	Sept 8–12	Fair
Chinese Cling	Shanghai, China	1850	Imported by Charles Downing	White	do	Cling	Aug 25–29	Good
Climax	Florida	1886	G L Taber	do	Soft melting	Semifree	Late	Do
Crosby	Billerica, Mass	1876	Mr Crosby	Yellow	Melting	Free	Late midseason	Do
Early Crawford	Middletown, N J	1820 (?)	William Crawford	do	do	do	Aug 17–20	Very good
Early Elberta	Kaysville, Utah	1908	Sumner Gleason, Stark Bros Nursery	do	do	do	Midseason	Good
Early Wheeler	McKinney Tex	1906	E W Kirkpatrick	White	Nonmelting	Cling	July 11–20	Fair
Elberta	Marshallville Ga	1870	S H Rumph	Yellow	Melting	Free	Aug 21–27	Good
Engle	Paw Paw, Mich	1875	C C Engle	do	do	do	Aug 24–Sept 3	Do
Eureka	Louisiana	1870	Unknown	White	Soft melting	Semifree	July 27–Aug 5	Do
Foster	Medford, Mass	1857	J T Foster	Yellow	Melting	Free	Late midseason	Very good
Frances	Texas	1895	L T Sanders	do	do	do	Sept 3–8	Good
Gaume	Live Oak, Calif	1913	Louis Gaume	do	Nonmelting	Cling	Late midseason	Do
Gold Drop	Michigan	Unknown	George W Griffin	do	Melting	Free	Sept 8–10	Do
Greensboro	Greensboro, N C	1891	W G Balsey	White	Soft melting	Cling	July 13–18	Do
Hale Early	Ohio	1850	Mr Moss Introduced by Hale and Jewett Nursery	do	do	Semifree	July 23–28	Do
Heath Cling	Unknown	1760–70(?)	Unknown	do	Melting	Cling	Sept 22–27	Do
Hiley	Marshallville, Ga	1886	Eugene Hiley	do	do	Free	Aug 8–14	Very good
Illinois	North Alton, Ill	1910	E H Riehl	do	do	do	Aug 17–25	Do
Iron Mountain	New Jersey	1890	Unknown	do	do	do	Sept. 21–25	Fair to good
J H Hale	South Glastonbury Conn	1912	J H Hale, W P Stark	Yellow	Firm melting	do	Aug 23–30	Good
Kalamazoo	Kalamazoo, Mich	1869	J N Stearns	do	Melting	do	Aug 8–31–Sept 3	Do
Krummel	St Louis, Mo	1895	Mr Krummel	do	do	do	Sept 23–27	Do
Late Crawford	Middletown, N J	1815(?)	William Crawford	do	do	do	Sept 5–9	Very good
Lemon Free	Ohio	1885	Unknown	do	do	do	Sept 12–19	Good
Lola	Mexia, Tex	1876	J W Steubenrauch	White	do	Semifree	Medium early	Do
Lovell	Winters, Calif	1882	G W Thissell	Yellow	do	Free	Late midseason	Do
Mayflower	North Carolina(?)	Unknown	Unknown	White	Soft melting	Cling	June 19–30	Fair
Mountain Rose	Morristown, N J	1851	Dr Marvin	do	Melting	Free	Aug 16–19	Good

Tuskena (Tuscan)	Mississippi	1873	Unknown	do	Nonmelting	Cling	Early midseason	Do

[1] The terms "melting" and "nonmelting" are used to denote the degree of softness of the flesh of ripe fruits All freestones have either firm or soft melting flesh, and some early ripening clingstones (Greensboro) have soft, watery, melting flesh, while the flesh of clingstone varieties of the commercial canning type, such as Phillips, have firm nonmelting flesh

[2] The ripening dates are those for the U S Department of Agriculture orchard at Beltsville, Md, in 1936, a normal season Where the variety listed did not fruit, the general season is indicated as early or midseason

As the commercial industry spread, there was always a demand for varieties that would succeed best under various soil, climatic, and other environmental conditions occurring in the different peach-growing sections. In northern regions growers were interested in varieties hardy in wood and bud to withstand low winter temperatures, while in the more southern latitudes they were interested in varieties that would stand summer droughts and high temperatures and with fruit that would retain its firmness during shipment to distant markets. Then came the scourge of disease and insect troubles—peach yellows, leaf curl, brown rot, curculio, and the peach-tree borer. What varieties, if any, would prove most resistant to these troubles?

During the period 1850 to 1900 a large number of varieties were selected from seedlings as worthy of introduction. The list of 50 varieties given in table 1 contains the names of many that still have an important place in the peach sections of the country. They also served as parents for varieties introduced during the last 20 years. The dates of origin of these varieties cannot be accurately obtained in all cases. They are approximately correct and are given to show the length of time the variety has been under orchard test.

It will be noted that the geographical origins of these varieties include nearly all of the States east of the Mississippi between the Great Lakes and the Gulf. Peach growing as an industry was truly widespread in the United States by the end of the nineteenth century. The need for new varieties to replace those that had been under trial was apparent during the period from 1900 to 1910. This was principally due to the fact that peach growing was rapidly developing into an industry for specialists. When the business of peach growing had developed to a point where it was necessary to ship the crop to consuming markets several hundred miles from the orchards, varieties had to be chosen that would stand up in transit and compete successfully with varieties from other sections on the market at the same time. The freeze of 1899 had wiped out many orchards in the North and emphasized the need for varieties that would withstand cold for the commercial orchards of the future. More recent freezes of the winters of 1917–18, 1933–34, and 1935–36 have reemphasized the importance of developing varieties for the North that are more cold-resistant than many now being grown.

Work of Private Breeders in the United States

During the last 30 years there has been an increasing recognition by peach growers of the need of originating new varieties better adapted to meet local requirements in various regions. This is well illustrated by the more recent work of J. W. Steubenrauch, of Mexia, Tex., who developed the Carman variety from pits planted in 1889. It is one of many important commercial peach varieties originated in Texas during the period 1850–1900. Mr. Steubenrauch, now 84 years old, summarized his work in a letter on May 13, 1936.

He planted his first orchard of peaches in central Texas in 1879. There were many kinds available to the growers, mostly what were then called Indian peaches, some good, but not very suitable for general markets. Recognizing the need for varieties of the best quality ripening from early to late season, he bought many trees of new

varieties from various parts of the country. In the course of a few years he had 100 or more distinct varieties growing in his orchard. From this number there were not more than about 10 that would be called good varieties for that period, mostly suitable for home use. Among a lot of Elberta trees planted in 1884, he found one tree that he considered superior to all the rest, producing finer fruit more regularly. Having a fine later peach that was part Indian stock, named Belle October, he decided to bud from the fine Elberta and Belle October parents on a single stock away from all other peach trees. From the two varieties blooming together with bees as pollinating agents, he obtained fruit and seeds of the early and late varieties.

Planting the seeds from the best peaches of both varieties, he produced some fine new seedlings in season from the time of Elberta till late in October. One of the leading ones is the Frank, which was named for Frank P. Holland, publisher of Farm and Ranch. This peach bore a heavy crop again in 1936, making 32 years of continuous annual production. Mr. Steubenrauch describes this variety as a fine yellow-red cling, ripening in the middle of August in central Texas.

In addition to the Frank he produced six others that he considers fully as good. These are Tena, Lizzie, Liberty, Anne, Barbara, and Katie.

These varieties, which have been tested in southern latitudes as well as in some of the Northern States, have demonstrated superior germ plasm and are worthy of note for possible use by breeders of peaches.

The man who discovered and introduced the variety that took the lead in commercial peach production in this country from 1910 up to the present was the late S. H. Rumph. He produced the Elberta from a seed of Chinese Cling planted at Marshallville, Ga., in 1870. Curiously enough, another seed reported to have come from the same Chinese Cling tree, planted in the same year by S. H. Rumph's brother, L. A. Rumph, also of Marshallville, Ga., gave rise to the variety called Belle of Georgia. Today these two are still among the leading commercial varieties. They are of particular genetic interest because the Elberta, a yellow, and the Belle, a white, are reported to have come from seeds of the white-flesh Chinese Cling, and because they are promising varieties for use as parents in breeding work.

Hiley, a probable seedling of Belle, originated with Eugene Hiley, also of Marshallville, Ga., in 1886. Today the Hiley variety ranks second to Elberta as the leading peach of the Southeastern States. It has demonstrated its value as a possible parent in peach improvement because of its high quality and its ability to produce fruits in those southern latitudes where warm winters may be a factor in delaying spring growth and blossoming (fig. 8).

One of the most important varieties that became prominent in the period 1900–1920 is J. H. Hale. This variety was discovered by J. H. Hale as a single tree in a lot of Early Rivers peaches shipped to him by David Baird, of Manalapan, N. J., and planted on his farm at South Glastonbury, Conn. Buds from this tree were taken later to Hale's farm at Fort Valley, Ga. Here the variety also showed great promise as a commercial peach, and it was introduced by Hale through the W. P. Stark Nursery in 1912. By 1925 it ranked fourth

among the freestone varieties grown for fresh fruit in the United States. Present opinions differ as to its value as a commercial variety. It has most of the essential fruit characters of a good commercial peach, but the trees are somewhat dwarfish on some sites and locations, not particularly hardy in wood and bud, and not highly productive. The flowers are pollen-sterile, a serious fault that affects productivity when the variety is planted in solid blocks By and large, the variety

Figure 8.—In southern peach-growing latitudes and in regions with warm winters some varieties are much slower than others in coming out of the rest period after mild winters. On the left is a row of Hiley in full bloom, and on the right a row of Early Rose still dormant. Photographed at Marshallville, Ga., April 12, 1932, a year of marked prolonged dormancy for this region. This is about 5 weeks later than average full bloom.

is not as widely adapted nor as productive as one of its probable parents, the Elberta, and it has not displaced that variety from the position of America's no. 1 commercial peach. However, certain characteristics of the J. H. Hale make it of particular interest to the peach breeder and cytologist. Some genetic features of this variety are discussed later in this article.

Hale introduced another variety, the Early Rose, which proved its commercial importance as an early shipping peach for the Southern States. This soft-flesh cling of fair quality and good color was discovered as a chance seedling growing at Fort Valley, Ga., by John H. Baird, of the Hale farm.

Controlled crossing has been carried on by J. E. Markham, of Xenia, Ill., who, beginning in 1925, developed and introduced to the trade Vivid Globe (Yellow Globe × J. H. Hale), Canadian Queen

(Canadian Banner × Early Elberta), Markberta (Halberta × Canadian Queen), Markham Cling (Golden Cling × Jap Cling), Mark Late (Canadian Queen × Markberta), Globe Haven (South Haven × Vivid Globe), Markham Jewel (Imperial Elberta × Canadian Queen), and Halberta (J. H. Hale × yellow seedling). Most of these varieties have not been widely tested.

Private breeders played a very important part in the work of selecting peach varieties of promise not only from a commercial standpoint but also from that of further improvement of the peach by systematic breeding. Space does not permit listing the many individuals who have been constantly on the watch for the appearance of superior sorts originating as chance seedlings and who subjected the seedlings to careful test. The names of many of these men are given in table 1, together with the description of the varieties they introduced.

Peach Breeding at Public Institutions in the United States

Breeding work with peaches was started at the New York (State) Agricultural Experiment Station at Geneva, N. Y., in 1895, when open-pollinated seeds of the Elberta were planted. No crosses were made until 1910. Work was also begun at the Iowa Agricultural Experiment Station in 1905, when the late S. A. Beach planted some selfed seeds of the Chili in an attempt to develop hardy varieties that would prove resistant to cold. Crandall, at the Illinois station, began work on the development of new varieties about 1907. At the same time work was started at the California station on the development of peach varieties that would be satisfactory for growing in the warm climate of southern California. By 1914 several States had provided funds for peach breeding at a number of State institutions. Peach-breeding studies were begun at the New Jersey station in 1914. The present peach-breeding work in Michigan started at the South Haven Horticultural Experiment Station in 1924. The United States Department of Agriculture began cooperation in peach breeding with this State in 1919 and later cooperated in the work in California. By 1930 there was considerable interest in developing new varieties of peaches by systematic breeding, and variety improvement work has recently been started in a number of other States.

The first promising varieties that resulted from this early station work for replacement of unsatisfactory kinds were introduced in 1925 by the New Jersey station and also by the Horticultural Experiment Station at Vineland, Ontario, Canada. A list of new varieties introduced as a result of systematic breeding and selection work by State and Federal agencies and by the Ontario station for the period 1900–36 is given in table 2.

Work is now being carried on at the various State experiment stations to meet special requirements of the peach industry in the several States. Following table 2 is a summary of the crosses being made and the progeny obtained, beginning with States in which the work has been in progress for the longest time.

TABLE 2.—*Peach varieties developed and introduced by public institutions*

State or Province	Variety introduced	Parentage	Breeder	When crossed	Year named and introduced
California	Babcock	Strawberry × Peento	Citrus Experiment Station, E. B. Babcock and C. O. Smith	1907	1933
Iowa	Polly	Chili (selfed ½ open pollinated)	Iowa Agricultural Experiment Station	1915	1932
Michigan	Halehaven	J. H. Hale × South Haven	South Haven Horticultural Experiment Station	1924	1932

	Vimy	Elberta × Arp	do	1916	1925
	Viceroy	Vaughan × Early Elberta	do	1919	1930

New York

To date 65 varieties, 8 seedlings, and 5 P. I.[3] numbers have been used in breeding work at the Agricultural Experiment Station at Geneva. Champion was used 8 times, Crosby 8, Elberta 27, Greensboro 13, Chili 11, Hunter (nectarine) 19, J. H. Hale 11, Krummel 8, Livingston 12, Rivers Orange (nectarine) 10, Rochester 10, South Haven 10, Sure Crop (nectarine) 31, and Veteran 9. There were in all 333 crosses, 24 selfs, and 13 open pollinations. Of the 400 seed-

[3] Trees imported by the Division of Foreign Plant Introduction as well as seedlings grown from seeds brought in are distributed for testing under numbers preceded by the initials P. I.

lings set in the orchard, 307 have originated from crosses made since 1922. Many of the seedlings are just beginning to fruit, and therefore their full history is unknown.

New Jersey

From the work started in 1914, 20 new varieties had been introduced up to the spring of 1936. In addition to these there are 17 unnamed but specially selected peach seedlings showing considerable promise that are now being grown in State-wide commercial tests During the period 1923 to 1936, 6,257 seedlings had been obtained by crossing, selfing, and open-pollinating varieties of peach and nectarine possessing desirable characteristics. Of this number 1,064 have been retained for further study. Approximately two-thirds of this number are of J. H. Hale parentage.

Iowa

One of the objectives of the breeding work at the Iowa Agricultural Experiment Station is to test the feasibility of making interspecific crosses with stone fruits. About 100 potted trees grown in the greenhouse are being utilized in this work. Varieties of *Amygdalus persica*, including nectarines of *A. davidiana* (Carr.) Zabel as well as hybrids between these two species, are being grown. From the crosses made, approximately 75 promising seedlings are now being studied in the field. These include Chili (fourth generation) open-pollinated, Chili (third generation), Bailey × *A. davidiana*, J. H. Hale × *A. davidiana*, and Chili (third generation) × *A. davidiana*.

Illinois

Of the first series of crosses made by Crandall at the Illinois station all have been discarded except Illinois 146, 148, and 101. These are being propagated for further testing under semicommercial conditions. The quality of all three of these is high, but they probably are somewhat lacking in the firmness of flesh that a commercial peach must possess.

Michigan

From the peach-breeding work begun at the Michigan station in 1924, one promising commercial variety, Hale Haven, a cross of J. H. Hale × South Haven, was introduced in 1932. This is a large yellow freestone maturing 17 days before Elberta and about the same time as South Haven. It is considered to be an improvement over the latter variety because of its higher color, thicker skin, and perfect freestone condition. The number of seedlings being grown at the present time from the crosses made during the period 1924–36 is 2,076. During the period 1924–30, 700 seedlings were obtained from crosses of J. H. Hale with a number of commercial varieties important in Michigan, such as Banner, Kalamazoo, Elberta, South Haven, and New Prolific. Of this list only 15 had superior horticultural value.

Work is now under way in an attempt to develop some clingstone varieties of canning types suitable for Michigan conditions. At the present time there are under observation 359 seedlings from crosses where one parent is freestone and the other cling, or where both parents are cling.

California

The work on peach breeding at the California Agricultural Experiment Station at Davis has been confined in recent years (1930–36) largely to developing a satisfactory type of nectarine for canning. A large number of seedlings are now being grown on the station grounds from about 1,310 crosses of nectarine × nectarine and nectarine × peach. Among the varieties of nectarines used as seed and pollen parents are Stanwick, Ansenne, Diamond Jubilee, Sure Crop, Quetta, Boston, Dixie, New Boy, Goldmine, and Lippiatt. Peach varieties used either as seed or pollen parents in crosses with these nectarine varieties are Lovell, Muir, Late Champion, Red Cling, Elberta, Late Crawford, J. H. Hale, Fay Elberta, and Rochester. In addition there is a very excellent collection of over 300 named and P. I. numbered varieties of peach and nectarine as a source of breeding material.

Breeding work with peaches was begun in 1907 at the University of California Citrus Experiment Station, Riverside, to develop varieties for growing in southern California. In this section many of the older varieties of cling and freestone types do not start growth sufficiently early in the spring to secure normal development, and shedding of blossom buds is common following warm winters. The Babcock peach, which was introduced in 1933 by G. P. Weldon, of the Chaffee Junior College, and by the University of California, was the result of the early work started by E. B. Babcock and C. O. Smith and continued by J. W. Lesley. The special value of the Babcock peach lies in its easily broken dormancy. It is an early white freestone of fair size and good quality. In recent years other crosses have been made, using as seed parents various cling and freestone varieties, and pollen from Honey and Peento types and varieties in which dormancy is easily broken. The Babcock is also being used in these crosses. From this work about 12 seedlings have shown promise and are being carried for further testing. Sims pollinated by P. I. 32374 has given a very promising yellow cling. Sims is a variety characterized by a short rest period.

Massachusetts

Breeding work at the Massachusetts station was begun in 1918. The progeny from most of the crosses made in 1925 and 1926, using as female parents varieties that showed considerable hardiness, has been discarded as unsatisfactory for growth under Massachusetts climatic conditions. There are 2,460 seedlings now receiving special study, mostly of a genetic rather than an immediately practical nature. However, a number of promising seedlings have been selected for further testing. In 1931 and 1932 over 2,000 seedlings were obtained in crosses with Belle, Champion, and Gold Drop in studying the problem of linkage between flesh adherence to stone and flesh texture. Some crosses have also been made in a study of the inheritance of bark color.

Virginia

In recent years studies have been made on the progeny of a smooth-skinned Crawford seedling obtained by selfing, when it was crossed with such varieties as J. H. Hale, South Haven, Rochester, Oriole, Golden Jubilee, Elberta, and Gold Drop. The object of the crosses

is to obtain a variety of high quality possessing bud hardiness. Orchard and potted trees are being used. From this work, as well as that previously done with open-pollinated and selfed Elberta, about 15 seedlings of horticultural value have been obtained.

Texas

Breeding studies were begun at the Texas Agricultural Experiment Station, College Station, Tex., in 1935. This work has for its purpose the development of varieties suited to peach-growing districts of Texas where the winter temperatures may not be low enough to give the proper amount of chilling required for best development of varieties that do better in more northern latitudes. Hiley, Pallas, Belle, Early Elberta, Anna, Indian Free, Slappey, and Florida Gem have been used in the crosses.

United States Department of Agriculture

Peach-breeding work in the Department was started in 1919. The early crosses were made at the branch experiment station of the Michigan Agricultural College at South Haven, Mich. Later, crosses were made at the United States Plant Introduction Garden at Chico, Calif. Since 1922 the work has been carried on in the Santa Clara Valley, principally in the experimental orchard at Leland Stanford Junior University, Palo Alto, Calif. Work has recently been undertaken at the United States Horticultural Station at the National Agricultural Research Center, Beltsville, Md., where some 150 varieties are available for study. During the past year 79 separate crosses were made, usually high-quality cold-resistant varieties.

New varieties that have been introduced as a result of the work in California are Leeton, Maxine, Stanford, and Ellis. The Leeton is a selected seedling of Leader grown at Palo Alto from pits imported by Frank Dixon from Leeton, Australia. Maxine is the product of a cross made at South Haven, Mich., between Lemon Free and an unnamed early-ripening seedling of noticeable bud hardiness. The Stanford, a Hauss×Phillips hybrid, is a canning cling peach ripening in season with Phillips. The Ellis, a cross of Phillips×Linden, is also a canning cling type ripening about a week ahead of Stanford. The introduction of these varieties has been based largely upon their behavior under California conditions. The two freestone varieties are worthy of testing under eastern conditions. The Leeton ripens about in season with Triumph and shows promise of being a better early peach than the latter variety. The Maxine is a yellow-flesh variety of high quality, ripening just after Rochester. It has proved to be quite cold-resistant in bud during two recent severe winters (1934–35 and 1935–36) at Beltsville, Md.

A large number of hybrids have been produced since 1922, and these are under test in the experimental orchard at Palo Alto, Calif. Some of the more promising of these hybrids are being tested at other places in California and, in a limited way, in a number of orchards in the eastern United States. Nearly all of the imported freestone varieties produced in this California breeding work are being tested at Beltsville, Md. The seed parents are given in the following list, together with the number of hybrids developed from each parent: Elberta 11,

Hauss 5, Horton Rivers×Chili 8, J. H. Hale 11, Illinois 2, Leader 5, Libbee 8, Lovell 7, Maxine 3, Miller Late 2, Mira 1, Muir 15, Newhall 3, Ontario 4, Paloro 18, Phillips 5, Pratt-Low 10, Salwey 44, Selma 3, St. John 2, Tuskena 14, Uneeda 1, Yellow Free 2, Yellow Transvaal 18.

In addition to the more common commercial varieties, a large number of Department introductions having desirable characteristics and showing considerable promise for breeding have been used. Among these are a Chinese introduction (P. I. 43289) and a Spanish cling (P. I. 43570T2). The varieties listed above as female parents have also been used as pollen parents in a good many reciprocal crosses. Backcrosses and intercrosses have also been made with first-generation hybrids. Studies are being made on the progeny of 234 separate and distinct crosses of named varieties and hybrids. From this group of hybrids a number of promising freestone varieties have been obtained that have characteristics superior to a number of the present commercial varieties. Some are promising canning clings, while others show marked resistance to delayed foliation and are adapted for growing in warmer climates where the present commercial varieties do not produce satisfactory annual crops. Combinations have been made between important commercial varieties subject to delay in foliation and such introduced varieties as Yellow Transvaal and St. Helena, which have less prolonged dormancy, in the hope of transmitting this desirable character to the progeny.

In 1909 Shamel and associates (*29*) noted some striking limb variations in studies of freestone varieties in California, and more recently he has discovered some early- and late-ripening strains among peach varieties. Weldon (*31*) has also reported finding several limb variations in orchards in the same State. It appears that some varieties of peach are less stable than others. While very few color sports of peach have been found to date, it would not be surprising if more should be found when careful search is made.

Peach Breeding in Other Countries

Canada

Since 1914 peach breeding has been carried on at the Ontario Horticultural Experiment Station, Vineland, Ontario, to meet the needs of the market and climatic conditions of southern Canada, especially to secure varieties giving a seasonal succession of ripening. Open-pollinated seedlings have been grown in considerable numbers. Some hybridizing has also been done. Earlier ripening Elberta types with attractive fruit of high quality were sought. In all, 13,106 seedlings were grown during the period 1911–36. Of these, 144 have horticultural value. Six varieties were introduced during the period 1925–30. Two of the most promising, Valiant and Vedette, are Elberta seedlings.

From 1918 to 1922 approximately 2,200 open-pollinated seedlings of Elberta were fruited. A second lot of 1,000 Elberta seedlings bore a marked resemblance to the parent tree in growth characteristics and in fruit. Probably 15 to 20 percent could have been propagated and distributed as Elberta, while approximately 3 percent had white flesh, and 15 percent were semiclings or clings. A fair number were

moderately good, none exceptional, the majority being of Elberta quality or poorer. The variation in season from Elberta was slight, ranging from a week earlier to a week later. Five hundred and fifty open-pollinated seedlings of Lemon Free were almost identical with the parent. Only a very occasional tree bore fruit with even a suggestion of color other than the yellow. Seedlings of New Prolific, Reeves, and Early Crawford were very much like their parents. The fact that open-pollinated seedlings of peach came so true to type when the pits were taken from an orchard in which there were upward of 150 varieties, thus affording every opportunity for natural crossing, suggests that the peach is usually self-pollinated under orchard conditions.

England

Experiments with peaches and nectarines were begun at the John Innes Horticultural Institution, Merton, England, in 1911. The object was to investigate the genetic composition of fruit trees by raising selfed offspring. The varieties used were Royal George, Blood Leaf, and Lord Napier nectarine. The results obtained will be considered later under the discussion of genetic relationships in the peach.

Australia

The work on production of improved varieties of dessert peaches in New South Wales is located at Hawkesbury Agricultural College, Richmond, while that on improved varieties of canning peaches is at the Yanco Experiment Farm, Yanco. Breeding at the Yanco Farm with peaches was begun in 1928. One of the principal objectives was the development of better varieties for canning that would possess high quality, large size, good yield, and freedom from red around the pit. There is a need for early canning varieties to come in immediately after the late apricots are harvested. Table freestone types are also sought in New South Wales, though not specifically in the breeding program at Yanco. The following varieties have been used in crosses as sources of open-pollinated seeds: Golden Queen, Leader, Paloro, Pullars, Sims, Tuskena, Goodman Choice, Locksley Perfection, and Phillips (Victorian strain). Of these the greatest promise as parents has been shown by Golden Queen, Phillips, Tuskena, and Sims (Victorian). Goodman Choice has desirable habits, and Pullars excels in yield but is red around the pit. Leader, a freestone, is one of the best parents. Dessert types that are being planted for orchard trial are Phillips × Triumph, Tuskena × Leader, and La France × Elberta.

At the Hawkesbury Agricultural College, seedlings of Goldmine (nectarine) × Triumph (peach), Blackburn × Triumph, and Elberta × Wiggins have produced fruit of some promise as freestone dessert peaches. With nectarines, work is under way to improve on the standard variety Goldmine. The varieties used as pollen parents are Mrs. Chisholm, W. C. Frip, and Irrewarra.

Morocco

A fruit and vegetable experimental laboratory was established in 1933 for the study of horticultural genetics. Its activities extend to the six experiment stations of the Lacarelle group, distributed in the

different fruit-producing regions of Morocco, as well as to the official experimental gardens of the protectorate. The peach-breeding work has a definite objective, the production of new varieties of high quality adapted to local climatic and soil conditions, as well as stocks resistant to certain diseases, such as gummosis. The work to date has been concerned principally with the study of the hereditary characters of varieties that would appear to be the best parents. A number of hybrids have been produced and are under test. Four forms of the Atlas peach are being used as stocks.

Some Objectives in Improvement of Peach Varieties by Breeding

In surveying the long list of peach varieties available for planting, many are found with very desirable characteristics but for one reason or another not entirely satisfactory from the standpoint of the commercial grower or the home fruit gardener. The fault is often determined by the fruit-growing region in which the particular variety is grown. In one region it may be lack of resistance to winter cold, in another it may be unproductiveness; in still another a peach may prove to be a good bearer with satisfactory cold resistance but lack fruit size and quality. If suitability for canning is the principal requirement in a section, a variety must be judged entirely from this standpoint. Varieties poorly suited for one region or purpose may be entirely suitable for other conditions.

In this article the Elberta has been mentioned as our most important commercial variety, but it lacks some desirable characteristics. It is adapted to a wide range of soil and climatic conditions and is an excellent shipping peach, but it does not have the high fruit quality nor the desired degree of resistance of the tree and blossom buds to low winter temperatures. Where the characteristics of this variety have been combined by breeding with those of a variety more hardy in bud, the results have been promising. A few varieties have been obtained that are of higher quality and more cold resistant in bud than Elberta, but they are not so widely adapted to the fruit-growing regions of this country. Seedlings of the Elberta have been found that ripen ahead of the parent and have fruit of higher quality and more attractive in appearance. So far, when all characteristics are considered, a peach truly better than Elberta has not been found; but if by proper combination of characters a superior variety that is as widely adapted can be produced, it will be a major contribution to American fruit culture. To secure a hardy commercial variety for the colder peach-growing sections of the United States is another most important objective in fruit improvement.

It has long been known that varieties of the so-called Crawford type are of very high quality but not especially productive, and very tender in bud. Varieties of this type have passed out of commercial production because they possessed these unprofitable characters. Attempts should be made to introduce Crawford-type fruit quality or its equal into other varieties, or to combine the hardiness and productive qualities of other varieties with those of the Crawford type. Progress has been made in this direction by using St. John, a Crawford

type of high quality but not particularly strong in tree character and cold resistance in bud, in crosses with Admiral Dewey, an old variety that is particularly hardy in bud, with small, fuzzy, unattractive fruits. A very promising hybrid has been thus developed in the breeding work of the Department of Agriculture.

The J. H. Hale variety has many outstanding fruit characteristics, but it is lacking in vigor of tree, hardiness, and productivity. A cross of J. H. Hale × South Haven at the Michigan Agricultural Experiment Station has resulted in a hybrid showing decided improvement over the South Haven variety. Considerable breeding is under way, using the J. H. Hale variety as a parent. Accomplishments to date, while not entirely satisfactory, give promise for the future.

The raw material represented by varieties of peach in this country needs further reworking through breeding methods in order to obtain the desired combination of characters. In this material there are still many important characters lacking that may be found in varieties now growing in other parts of the world. The need of continuing to import material is apparent. An example is the quest for a variety that is not subject to delayed foliation. In climates with warmer winters than those of the fruit regions of this country, varieties are to be found adapted to such conditions. Such varieties should be introduced into this country for combination with our own. Progress has been made in California in recent years on this aspect of breeding work by the Department of Agriculture. Varieties of the peach of the St. Helena and Transvaal types, introduced respectively from the Island of St. Helena and from South Africa and crossed with our native varieties, have given results that would indicate that the problem of delayed foliation can be overcome at least to some extent through breeding.

There is need for more knowledge about the heritable characteristics of rootstocks for peaches. It has been observed that some varieties of a particular parentage are more susceptible than others to cold injury or to root disease. It is important to know which seedlings may be used as stocks to insure longevity, productiveness, and disease resistance. Work is now under way in the Department of Agriculture to determine the merits of seedlings of known varieties of peach and plum suitable for understocks (fig. 9).

As already indicated, methods must be devised whereby the seeds of early-ripening varieties of stone fruits can be made to germinate after crosses have been made.

Another important objective in stone-fruit breeding work is the development of superior varieties for canning and for drying. In California at the present time varieties of apricots suitable for canning are very much sought for. Varieties of peaches of the canning cling type that have been used for a number of years are not entirely satisfactory because of one weakness or another. Some otherwise satisfactory varieties develop red color in the flesh, especially about the pit, which renders them undesirable for canning. Pit splitting and gumming are other faults. Some of the canning varieties used at the present time are susceptible to mildew through the inheritance of glandlessness. Good types lacking such objectionable characteristics are needed for canning.

The method of approach to the problem of developing better varieties will involve basic studies in the inheritance and transmission of characters. An important part of the work, therefore, will be growing and studying progenies to determine the transmission of desirable as well as undesirable characteristics.

Very little work has been done from the standpoint of securing desirable characteristics through induced mutations. Polyploidy, or increase in the number of chromosomes, which has proved of special interest with other crops, has received little attention from workers in

Figure 9.—Peach rootstock effects. Early Hiley variety, fourth year in the orchard. The row on the right is on plum (*Prunus hortulana*), and the one on the left is on the widely used Tennessee "natural" peach stock. The dwarfing influence on the *hortulana* stock is apparent.

stone-fruit breeding. Some work has been done at the New York Agricultural Experiment Station at Geneva in an attempt to induce polyploidy in stone fruits through the selection of large pollen grains. This method has not yet yielded satisfactory results, but the studies need to be continued, with many other attacks on the general problem. No results have been obtained so far in attempts to cause mutations through heat treatments, a method that seems promising in corn breeding.

Some Genetic Facts Established in Peach Breeding [4]

In a collection of 100 or more peach varieties selected at random, the casual observer of the trees might think that they are all one variety. Among peach varieties in general there are no very marked differences in general tree characters. There are, however, distinct differences in size, shape, and color of leaves, in time of blossoming, in color and size of flower, in time of ripening, and in fruit characters. Genetic studies

[4] This section is written primarily for students and others technically interested in breeding or genetics

show these characters to be inherited, and in hybridization many of them appear in the normal Mendelian ratios. Cytological studies to date have not revealed how the factors governing these characters are linked, nor where they are located on the chromosomes, nor what the behavior is in the reduction division of the sex cells.

Connors (*4*, *6*, *7*), of New Jersey, was one of the first workers in this country to investigate some of the genetic relationships in peaches. He made crosses between some of the important commercial varieties in an attempt to gather information on inheritance of characters.

Inheritance of Flesh Characters

Flesh color.—The parents used by Connors in one series of crosses were Elberta and Early Crawford as yellow-flesh varieties, and Belle and Greensboro as white-flesh varieties. Early Crawford has small blossoms, Elberta medium, and Greensboro large. All are freestone except Greensboro, which is a soft semicling. An analysis of the progeny in the F_1 generation showed some interesting facts. All of the varieties used in the crosses were of unknown parentage, having originated as chance seedlings. Belle, a white, and Elberta, a yellow, are supposed to be F_1 descendants of Chinese Cling, with the pollen parent unknown. Greensboro behaved as a pure white in crosses, but when selfed no progeny was obtained because of the failure of the seeds to grow. St. John (yellow) × Early Wheeler (white) gave all white in the F_1, and St. John × Greensboro likewise gave all white F_1 seedlings. White flesh is dominant over yellow flesh. Crosses or self-pollinations of homozygous white-flesh varieties have yielded all white-flesh seedlings. Heterozygous whites have yielded three whites to one yellow. Yellows have given all yellow.

This work makes the supposed parentage of Elberta somewhat open to question. Elberta is a seedling of Chinese Cling, and the pollen parent is thought to be some variety like Early Crawford. If Chinese Cling were pure white, as might be suspected from its early history, then in a cross with a yellow variety the first generation seedlings should all be white. However, Elberta as the F_1 in this probable cross is yellow, while Belle, a seedling of the same variety (Chinese Cling) is white. The Chinese Cling parent of Elberta may not have been a pure white. The work at Vineland, Ontario, Canada, reported by Palmer (*26*), confirms that of Connors in showing that when a homozygous white-flesh peach has been used as one of the parents, all of the progeny will have white flesh. Yellow flesh behaved as a pure recessive. It is perhaps more significant in considering the parentage of Elberta that from 2,200 open-pollinated and selfed seedlings of that variety, there has been none with fruit resembling Early Crawford, the supposed pollen parent. Palmer has ventured the opinion that Elberta is a natural selfed seedling of Chinese Cling, a recessive yellow breeding true for that color.

Texture of flesh.—In the work of Connors, Elberta self-pollinated seedlings showed a high percentage of firm fruit. Wherever Elberta was used as a parent the result was a high percentage of firm-flesh seedlings. Belle × Early Crawford gave a relatively high percentage of firm-flesh seedlings. Soft flesh appears to be dominant over non-melting flesh. The character for producing the tough flesh so desirable

for commercial canning is present in Belle, Carman, and Early Crawford. Seedlings of these varieties, however, show red coloring of the flesh about the stone, an undesirable character from a canning standpoint.

Adhesion of flesh to stone.—Connors noted that freestone appears to be dominant over clingstone. In crosses between freestone varieties the progeny has been about two freestones to one cling or semicling. There are some varieties that are classed as semicling in which the adhesion of flesh to stone is not very great. In some of these groups such as Greensboro and Carman, the fruits in some seasons may be nearly free. Frequently, if the fruits are allowed to remain on the tree until well ripened, the flesh will almost completely separate from the stone. The true clingstone type of peach is that represented by varieties like White Heath and Red Bird, and the canning cling by types like Phillips and Paloro. Freestones crossed with freestones always gave a high percentage of freestones, the degree depending on the variety. Belle and Elberta carry a factor for adhesion of flesh to stone of about 33 percent. When freestones are crossed with clingstones a higher proportion of freestones than clingstones is obtained.

Inheritance of Other Characters

Foliar glands or nectaries.—The foliar nectaries of the peach are of interest because it has been shown that glandless varieties are more susceptible to some leaf diseases, particularly mildew, than varieties with glands. Some commercial canning cling varieties now grown in California, such as Paloro and Hauss, are glandless. These are quite subject to mildew in some seasons and in some locations. Rivers (*27*) reports that in crossing varieties having reniform glands with glandless varieties, he obtained an intermediate type, which was round or globose. Connors, in crossing some of our common American varieties, such as Belle, Carman, Elberta, and Greensboro, which are reniform, obtained seedlings all of which were reniform. When these varieties were crossed with varieties with globose leaf glands, the progeny was about 50–50 reniform and glandless. No glandless varieties were selfed, but Bailey and French (*2*) report all the progeny of a selfed glandless seedling were glandless. The F_1 hybrids of a cross between reniform and glandless varieties all have glands that are globose (fig. 10). The character is apparently incompletely dominant.

Tree habit.—In crosses at the New Jersey station between Greensboro, spreading type, and Early Crawford, upright type, the seedlings were all intermediate, none being the same as either parent. Seedlings of Early Crawford, self-pollinated, were all upright. Seedlings of Lola and Carman, which are spreading, were all spreading. The progeny from selfed Elberta gave ratios of 1 upright : 2 intermediate : 1 spreading. No dwarfs have appeared among the progeny of these varieties.

Size of blossoms.—With blossoms the blending type of inheritance is usually shown, with sometimes a slight apparent dominance of the small-blossom type. In all cases studied by Connors, the large blossoms and small blossoms were homozygous. Large crossed with small gave all medium, and the medium split up in a ratio of 1 : 2 : 1 in the F_2 generation. Large blossoms appear to be dominant in varieties

bearing them, while varieties with small blossoms give small blossoms in selfing. In crosses of large-petal types with small-petal types all the seedlings had medium-size blossoms. This appears to be a case of incomplete dominance.

Blooming date.—The majority of seedlings bloomed at practically the same season as the parents, but a few individuals bloomed earlier or later. Elberta and Belle, self-pollinated, gave some seedlings that commenced blooming as much as a week after the parents. Slappey is a late bloomer, and all of its progeny were late.

Ripening date.—The hybrids usually ripened about midway between the parents, and it is rarely the case that a seedling ripens

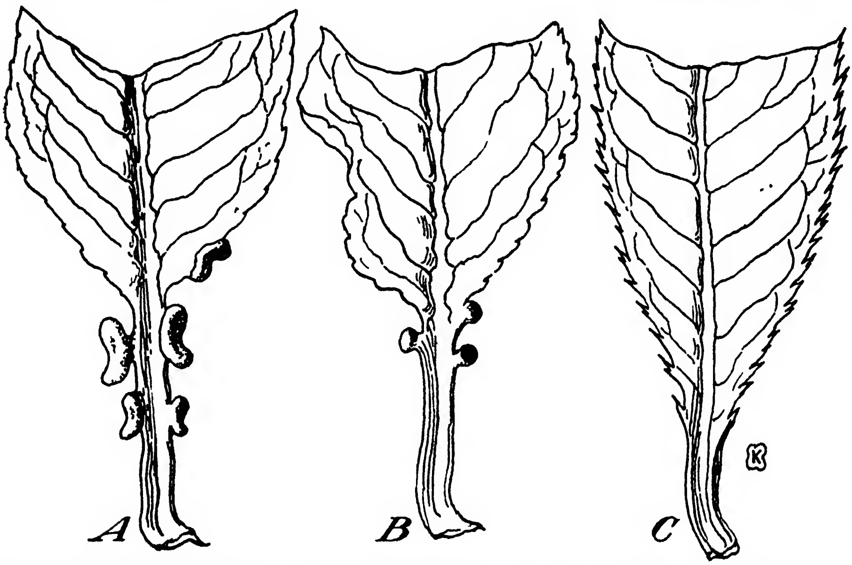

Figure 10.—Types of foliar nectaries in the peach and the nectarine: *A*, Reniform or kidney-shaped glands of Elberta peach; *B*, globose glands of Fitzgerald peach; *C*, eglandular leaf of Lippiatts nectarine.

earlier than the early parent or later than the late parent. The deduction is that the best chance to secure a new individual ripening its fruit at a certain date would be by crossing two varieties the mean of whose ripening dates would fall at the desired time. No marked differences in ripening dates were observed. The majority of the seedlings of the varieties used ripened about in season with the parents, with some slightly earlier and some later than either parent.

Size of fruit.—Parents with small-size fruit are to be avoided. Belle transmitted its character for good fruit size. Elberta seedlings are practically all large-fruited.

Beginning in 1921, Connors used the J. H. Hale variety in a number of crosses. During the period 1923–28, 42 crosses were made with this variety. Blake and Connors (*4*), reporting on the results of these crosses, state that the collection of characters in the J. H. Hale variety was as a group recessive to the characters in varieties such as Chili, Iron Mountain, Chinese Blood, and varieties with nonmelting type

of flesh. In the case of J. H. Hale × Chili the progeny of the cross so closely resembled Chili in every way that it was impossible to distinguish many of them from the pollen parent. In summarizing the evidence of inheritance of characteristics in the progeny of these J. H. Hale crosses, Blake and Connors drew the following conclusions: (1) Red flesh color about the pits is apparently dominant over absence of red at the pit; (2) watery melting flesh texture is apparently dominant over firm-melting flesh texture; (3) nonmelting flesh is recessive to both watery melting and firm-melting flesh texture; (4) blood red flesh was dominant over the absence of red; (5) heavy pubescence is apparently dominant over short or light pubescence; (6) oval-conic, oval-oblong, and round-pointed forms in Chili, Iron Mountain, Chinese Blood, Japan Dwarf Blood, and others were dominant over round; (7) full-dwarf and semidwarf growth habit was recessive to standard tree size; (8) early blooming, characteristic of *Amygdalus kansuensis* (Rehd.) Skeels, was dominant over the late blooming of J. H. Hale; (9) vigorous sucker development from the trunk and main branches characteristic of *A. kansuensis* was dominant over the slight sucker development of J. H. Hale.

Characters Transmitted by Certain Varieties

Elberta transmits large fruit size, yellow color, and firmness of flesh, freestone character, an extended period of ripening, and a slight tendency to sterility. The self-pollinated seedlings show better quality than that of the variety itself.

Belle is a heterozygous white and is able to transmit white and yellow flesh, a fair degree of firmness of flesh, a fair degree of freestone condition, variability in period of ripening and blooming, and a tendency to sterility.

Early Crawford transmits small fruit size, yellow flesh, a good degree of firm or tough flesh, a fairly high degree of freestone character, tender pubescent skin, and rather high acidity.

Greensboro transmits white flesh, good fruit size and color, hardiness in bud, softness of flesh, and a clingstone character.

Slappey transmits small fruit size, dry, mealy, yellow flesh, lateness of blooming, and nonadhesion of pulp.

Lola transmits small size, tendency to clingstone condition, and tough flesh.

In tree habit the white-flesh varieties are more vigorous in tree growth than yellow-flesh sorts.

Further genetic studies on the inheritance of characters in the peach may be helpful in tracing the origin of the aforementioned groups or races of peaches. This should be possible if prototypes of our present-day varieties could be located, such as the large-petaled, white-fleshed peaches of China, and the small and medium-petaled, yellow-fleshed types found among varieties more common in western Asia and the Mediterranean countries, and among the varieties now commonly grown in this country.

Genetic Studies in England

Work at the John Innes Horticultural Institution in England with the peach Royal George, having small flowers and small, eglandular, serrate leaves, when selfed gave a progeny of seedlings with small

flowers and eglandular, serrate-margined leaves. Royal George and its progeny proved to be susceptible to mildew.

The Purple Leaf variety of peach (Blood Leaf) with large flowers, purple leaves, reniform glands, shallow margin, finely serrate, when selfed gave a small number of progeny, all having large flowers, purple leaves, reniform glands, and leaf margin similar to type.

Selfed nectarine (Lord Napier variety) with large flowers, large leaves, reniform glands, and shallow crenate margin gave seedlings with flowers and leaves similar to the parent. A few of the leaves were almost serrate.

Two seedlings raised from a cross of Purple Leaf peach × Lord Napier nectarine had purple leaves, but the pigment was less intense than in the Purple Leaf parent or its selfed derivatives. This suggests that the purple pigment in the peach behaves as a dominant, but the reduction in the amount of pigment suggests a modifying factor.

Correlations

Hedrick (*17*) has pointed out a correlation between color of the inside of the calyx cup and the color of flesh of the fruit. When the calyx cup is greenish the fruit will be white, and when the calyx cup is a deep orange the flesh of the fruit will be yellow. An intermediate type is suggested by Connors in which the calyx cup is yellowish buff, and following this the color of the flesh will be white, but the tree carries a character for yellow flesh. This is true in the case of Belle.

Another correlation, according to Connors, is that between leaves and the color of the flesh. When the midrib and the veins of the leaves of a variety have a yellowish cast the fruit is yellow, but if the midrib or veins are pale green or whitish the fruit will be white.

Pollen Sterility

Most varieties of peaches are self-fruitful. Occasionally failure to produce crops may be due to pollen sterility, which is exhibited in a few commercial varieties, such as J. H. Hale, Halberta, Candoka, Mikado, and Chinese Cling.

Connors in 1921–22 examined over 330 seedlings in the fruit-breeding plots. J. H. Hale was the only variety that did not produce pollen, and about 50 percent of open-pollinated seedlings of this variety were pollen-sterile individuals. Progeny of some crosses with J. H Hale have also shown about 50 percent of sterile individuals, while in other crosses with this variety the progeny all produced pollen. It is suggested that this type of sterility is recessive to the fully fertile flower form. The failure of pollen-grain development in J. H. Hale has been found to be due to degeneration in the microspores some time previous to blossoming. Apparently there are strains of this variety that produce pollen and are self-fruitful, but whether these have arisen as somatic variations or have distinct ancestry is unknown.

Among seedling peach progenies examined the percentages showing pollen sterility were: Belle selfed 21 percent, Belle × Elberta 17, Elberta × Belle 14, Elberta selfed 13, Elberta × Early Crawford 7, Elberta × Greensboro 5, and Belle × Greensboro 4 percent.

Chromosome Numbers in Peach Varieties

The basic chromosome number in the sex cells in the genus *Prunus* is 8. The varieties of peach examined cytologically show the diploid (2*n*) number of chromosomes to be 16. So far as known, no triploid or tetraploid types have been discovered. If these have occurred in the past they have apparently not been propagated or were discarded in the search for new varieties. The fruit characteristics of the J. H. Hale variety might suggest a tetraploid condition, but insofar as is known they are not associated with tetraploidy.

The peach is rather a stable entity. No irregularities in chromosome behavior have been reported. Apparently reduction to the haploid number in the formation of the sex cells prior to fertilization and fruit development proceeds in a normal manner. Likewise in somatic cell divisions no conspicuous irregularities have been reported in chromosome behavior, and few varieties have been propagated as true somatic mutations.

The problem of self-unfruitfulness, which is very important in the case of other stone fruits and of apples, and which has stimulated considerable cytological investigation with these fruits, is relatively unimportant in the peach.

Nearly all of our commercial varieties are self-fruitful, that is, they set fruit with their own pollen. In a few instances varieties are self-unfruitful because of pollen sterility.

Our present-day varieties are largely considered to be chance seedlings, and many of them may have arisen as self-pollinated progeny of various types. Some doubtless are the result of natural hybridization. It is a fact, however, that many of these varieties are homozygous for the genes controlling several of the characters studied.

[5] The variety names in this and the following lists conform so far as practicable to the code of fruit variety nomenclature. However, among them there is a considerable number of introductions from other countries, selected strains of standard varieties tentatively designated, and other names applied temporarily, which cannot be made to conform readily to the code. The publishing of such names in this connection is not to be construed as the acceptance of them by this Department.

PLUMS

In the United States, as well as in Europe, the plum has long been recognized as one of the most delicious of fruits, and among the stone fruits it ranks next to the peach in commercial production. Many of the varieties of plums now cultivated in the United States have been introduced from many foreign countries, and when these are added to the native varieties they give plums the largest number and greatest diversity of kinds and species among the stone fruits. The fruits exhibit a wide range of size, flavor, color, and texture. The plants vary from small shrubs with drooping branches to trees of large size with large, upright branches, and some have great beauty as ornamental plants (*3*, *19*, *34*).

The common European plum, known botanically as *Prunus domestica* L., appears to have originated somewhere in southeastern Europe or western Asia, probably in the region around the Caucasus and the Caspian Sea. Although it is called the European plum, De Candolle, who summarized the history of these stone fruits, is very doubtful whether *P. domestica* is indigenous to Europe. According to the earliest writings in which this plum is mentioned, the species dates back some 2,000 years. Another Old World plum species, probably of European or Asiatic origin, is the damson plum, *P. insititia* L. This species seems to antedate *P. domestica*, as is suggested by the finding of damson plum pits in ancient ruins. The ancient writings connect the early cultivation of these plums with the region around Damascus.

It is not known just when European plums were introduced into North America, but probably pits were brought over by the first colonists. It is reported that plums were planted by the Pilgrims in Massachusetts, and importations were made by the French into Canada. These European plums have done remarkably well in the New World, and today they constitute the most important group grown commercially for canning and drying.

The native American plums were doubtless used for food by the Indians long before the white man set foot on the shores of this continent. Reports of early explorers mention the finding of plums growing in abundance. According to the descriptions of the early settlers, these plums were inferior to the domesticas of the Old World in quality, so that the colonists soon began importing varieties from Europe. As a result, European plums soon became predominant in home fruit gardens as well as commercial orchards in the northeastern United States.

Another important species of more recent introduction into North America is the Japanese plum, *P. salicina* Lindl., which was domesticated in Japan and was introduced into the United States about 1870.

The Raw Material of the Plum Breeder

Cultivated varieties of at least 12 species of plums are to be found in American orchards or growing in the wild, but most of the important commercial varieties are confined to 4 of these species. A wealth of types, varieties, and species is available for the fruit breeder.

The best known and most important of these groups are varieties of *Prunus domestica*, the European plums and prunes. Unfortunately

they are not well adapted to regions with hot, dry summers or dry, cold winters. They are at home in the northeastern United States; in sheltered sections along the Great Lakes and in the Intermountain and Pacific Coast States they are at their best, as is evidenced by the extensive production of fresh fruit and dried prunes in this region. The European plums have been under domestication longest, and the

Figure 11.—Types of fruit in the group of *Prunus domestica*: *A*, Reine Claude, a high-quality plum of the Green Gage group; *B*, Bradshaw, formerly an important variety in the Lombard group of reddish plums used for canning and dessert, but being replaced by better varieties produced as a result of hybridization and breeding; *C*, Diamond, a blue plum of the Imperatrice group. The varieties of this group are of medium size, dark blue in color, with a heavy bloom.

fruits are notable for large size and attractive appearance. They vary in color from the green and golden yellow or the Reine Claude (Green Gage) and Yellow Egg groups to the red and dark purple of the

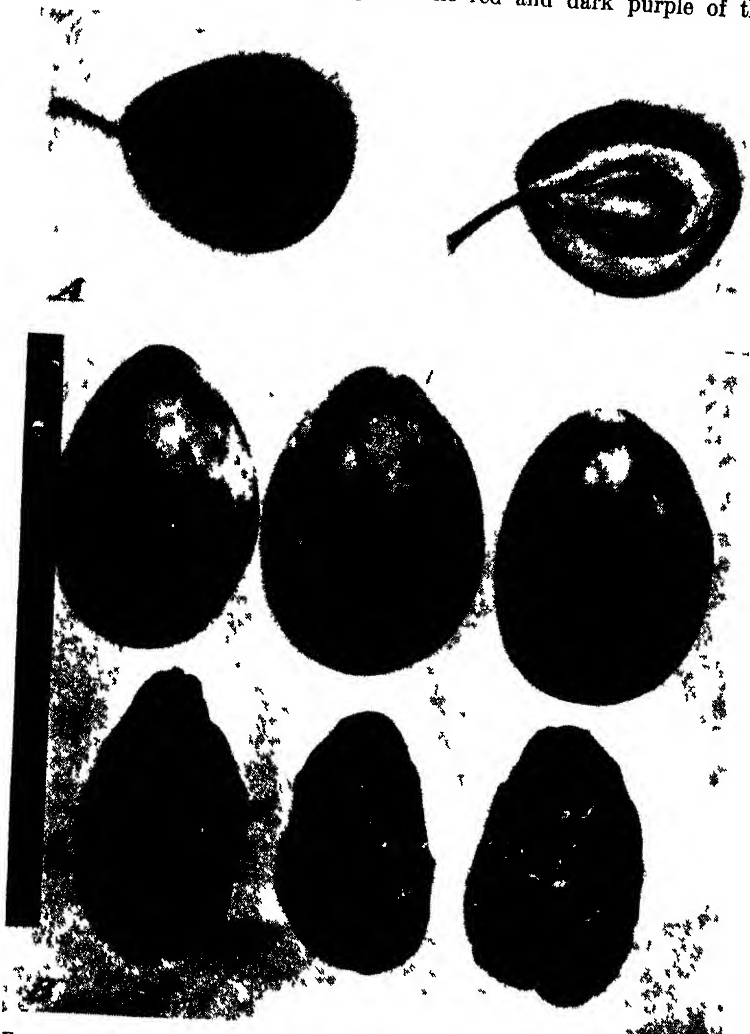

Figure 12—Some of the most important varieties of *Prunus domestica* used for making prunes: *A*, Italian Prune, showing the shape of the fruits in the prune group, *B*, some varieties that produce large prunes when dried

Lombard and Italian Prune (fig. 11). Italian Prune, Agen, Sugar, and Imperial Epineuse constitute an important group of European plums with firm flesh and high sugar content suitable for use fresh or as dried prunes (fig. 12). Other varieties, such as Tragedy, Reine

Claude, Bradshaw, and Golden Drop, are used principally for canning and dessert plums.

The damsons (*Prunus insititia*) of the Old World are quite different from the domesticas. The trees are more upright, compact, and dwarfish, the leaves and flowers are smaller, and the fruits are small, round, and quite tart, so that they are especially suitable for preserves and jams. Varieties of this group are hardy, vigorous, and productive, and the trees make good stocks for other species, being adapted to a wide range of conditions and thriving even when they are neglected. The Shropshire (fig. 13) and French are important

Figure 13.—Shropshire, one of the most important varieties in the damson group of *Prunus insititia*. This small blue plum, like others belonging to this group, is used principally for preserves.

blue damsons in this country, while the yellow Mirabelles are popular in France. The group as a whole has certain valuable qualities that appear to have been overlooked in breeding investigations.

The Japanese plums (*Prunus salicina*) are relatively new to North America, but in the short time since their introduction they have been widely planted and now rank second to the domesticas in commercial production. The trees are more spreading in habit than the domesticas or damsons, and in leaf and fruit characters they are very different, resembling the native American plums. The fruits are very attractive and are characterized by a yellow ground color overlaid by various shades of red. In some varieties the flesh color is a striking red, whereas fruit of the domesticas and damsons is green or yellow. Some recent hybrids of the salicina group (fig. 14) show distinct superiority

Figure 14.—Plum hybrids. *A*, *Prunus salicina* hybrid, variety Apple. This red-fleshed variety illustrates the round shape of the varieties of this species. *B*, America, a hybrid between *P. munsoniana* and *P. salicina*. *C*, Hybrid resulting from a cross of the purple-leaved plum *P. cerasifera* var. *pissardii* with *P. salicina* variety Abundance.

in flavor and in commercial possibilities over the early importations. Varieties of this group appear to be widely adapted in this country except in the very coldest climates. While the quality is not equal to that of the best domesticas, the fresh fruit is delicious in its blend of flavors. The varieties cross readily with one another and with the native americanas. Among the first Japanese plums grown in this country, Kelsey, Burbank, Abundance, and Satsuma are typical. The trees are hardy and productive, and they tolerate a variety of soils as well as climatic conditions. They blossom early, and the flowers are sometimes killed by late spring frosts.

Among the plums native to North America are varieties that are different in fruit and tree characters from the plums of Europe and the Orient. Botanists have divided the native American plums into a number of species and subspecies. Many of them have numerous characteristics in common, so that they overlap somewhat in present horticultural groups and classifications. *Prunus americana* Marsh., the most important of the native species, has a wide range of adaptation in this country, extending from Maine to Florida, westward to Utah, and northwestward into Manitoba. The tree is small, not as vigorous as the European, and it has rough, shaggy, grayish bark. The fruit is red, reddish yellow, or reddish orange, of pleasant flavor and good quality, but it has a thick, tough skin, and the flesh clings to the pit. De Soto and Weaver are among the typical cultivated varieties of americanas.

Other American species of minor importance from a commercial standpoint but of interest to the fruit breeder are the native varieties of *Prunus hortulana* Bailey; the Chickasaw plum, *P. angustifolia* Marsh.; and the wild-goose plums, *P. munsoniana* Wight and Hedr., of the southeastern and south-central United States, of which Wild Goose and Robinson are important varieties (*3*, *32*).

Other species of plums growing in North America are the Canada plum, *Prunus nigra* Ait., which is adapted to the north-central United States and Canada; the small beach plum, *P. maritima* Marsh., which grows along the eastern seacoast; and the western or Pacific plum, *P. subcordata* Benth., which grows east of the Coast Range in southern Oregon and northern California.

Finally, mention should be made of the myrobalan plum (*Prunus cerasifera* Ehrh.), a native of Europe, and the Simon or apricot plum, *P. simonii* Carr., a native of China. The myrobalan plum has been used a great deal in this country as a rootstock. Varieties of *P. cerasifera* and *P. simonii* are noted for their ornamental foliage.

This great collection of varieties and species affords an excellent opportunity not only for studying genetic relationships but for the development of new varieties by breeding. The study of the inheritance of characters in plums has, however, not been very extensive. This may be due in part to the fact that many varieties of plums are self-unfruitful; that is, they do not set fruit with their own pollen. This presents a problem to the fruit grower as well as to the plum breeder. It is, of course, impossible to obtain an inbred progeny to study the inheritance of characters if the blossoms cannot be selfed. Fortunately for both the breeder and the fruit grower, fruits can be obtained by cross-pollination, and not all varieties are self-unfruitful.

Objectives in Plum Breeding

It is a well-recognized fact that plum culture in North America has gradually been declining during the last 20 years. The reason for this is the failure to keep pace with the demand for fruits of high quality. Varieties that were satisfactory 25 to 50 years ago in most cases do not appeal to persons who have a taste for fruits of high quality. However, many varieties are still prized in the home garden even though they are not profitable to the large producers.

An important objective of any plum-breeding program should be the production of varieties of higher quality adapted to the various fruit regions of the country. None of the domestica plums of high quality can be grown satisfactorily south of Virginia or in the vast regions of the southwestern and south-central United States. Native American species grow in this part of the country, but their adaptability must be combined with the higher quality of other varieties and species. Work has been started in this direction, but it has met with failure because domestica and americana varieties have different chromosome numbers, and so far crosses between them have not yielded viable seedlings.

Further study is also needed in the direction of artificially increasing desirable mutations in plums. In a few instances desirable bud sports have been discovered, and careful search should be made to locate others.

In addition to high quality, consideration must be given to vigor, hardiness, and productiveness. Much has been accomplished in developing and selecting winter-hardy varieties for the Great Plains region. Similar work is needed to develop varieties adapted to regions with hot, dry summers.

Genetic and cytological studies are of first importance in initiating a plum-breeding program. Among the self-compatible varieties there is a wealth of valuable material that can be used as foundation breeding stock. Even before methods are developed for increasing fruitfulness in crosses between species, there is opportunity for research on the material within many of the plum species growing in this country.

Breeding Methods

The methods of breeding that have been described for the peach apply equally well to the plum. The breeder is confronted with the same problem of protecting the emasculated flowers in order to lessen damage to the pistils. With varieties known to be completely self-incompatible, emasculation is of course unnecessary, and time can be saved by omitting this operation.

The problem of seed germination and the production of new seedlings likewise confronts the plum breeder. The seeds from many crosses prove nonviable, and methods need to be worked out whereby a greater percentage of seeds can be made to grow.

Work of Private Breeders

The first work on plum improvement in this country consisted of attempts to obtain better strains of the native American plums by domesticating seedlings and selecting those most promising for size,

flavor, and productiveness. The most extensive work in this direction seems to have been started by H. A. Terry, of Crescent, Iowa. From about 1860 until the time of his death in 1909 he had originated over 50 varieties from native species. While there is little information available as to the breeding methods or parents used, it is certain that he produced more new varieties than any private breeder since his time. Some of the more important varieties introduced by him are Gold, Hawkeye, Hammer, Downing, Crescent, and Terry.

Work on the breeding of plums was begun by C. G. Patten, a private breeder and a contemporary of Terry in the same State, at Charles City, Iowa, in 1867. He was impressed by the great number of native plums found growing in the wild, became interested in domesticating some of these, and selected the best for the prairie and upper Mississippi Valley regions. Hardiness or ability to withstand cold winters was a factor to be considered in the selection of varieties for that region. He worked with the American species. One of his best selections was tested by the Iowa Agricultural Experiment Station and was introduced as the Patten plum.

Beginning about 1870, J. W. Kerr, of Denton, Md., began the study and testing of a large number of varieties of plums. He likewise was interested in developing new varieties from native plums. Among the varieties introduced by him are Choptank, Sophie, and Maryland.

In California, Luther Burbank began his plum-breeding work about 1880, at Santa Rosa. He introduced and produced many desirable types. Among the important varieties he developed from seed imported from Japan are Burbank, Abundance, and Satsuma. He was particularly interested in the Japanese types and did much to popularize the varieties of this species in California, and to lay the foundations for their later testing and use as important commercial varieties in that State. He likewise made a number of crosses between *Prunus salicina* and other species, producing Climax, Bartlett, and Wickson from *P. salicina* × *simonii*, and America (fig. 14) and Golden from *P. munsoniana* × *salicina*. Other varieties introduced that have been grown commercially in California are Giant, Splendor, Standard, Santa Rosa, Formosa, and Gaviota.

Hedrick and associates (*19, p. 170–171*) make the following comment on Burbank's work:

One cannot briefly catalog the new forms of plants that have gone forth from his private place in California; they must number well into the hundreds; his biographer, in 1905, said that Mr. Burbank has worked with over two thousand five hundred distinct species (Harwood, W. S., New Creations in Plant Life I. 1905). Among these have been practically all of the species of plums now under cultivation, from which have been obtained, according to Mr. Burbank, hundreds of thousands of plum-seedlings of which the breeder has selected a score or more of very distinct sorts, all interesting and a few of them very valuable. The many other fruits, flowers and forage plants which Mr. Burbank has sent out, each involving the handling of countless seedlings, cannot be mentioned here. Nor can his methods and results be discussed, except to say that in them he is a unique figure in plant-breeding and that they have been such that he has exercised a powerful influence toward the improvement of plants. The practical results of Mr. Burbank's work have been as great or greater than those secured by any other person in plant-breeding, yet they have been magnified out of all bounds in the popular press and his work has been caricatured by calling the man a wizard and ascribing to him occult knowledge. Of the plants introduced by Mr. Burbank

the proportion of really valuable commercial ones seems now to be small, but what he has done cannot be measured by money values; he has awakened universal interest in plant-breeding; has demonstrated that things unheard of before his time can be done with plants; and, all in all, his contributions in new forms of plants to horticulture and agriculture, in their intrinsic and educational value, make him the master worker of the times in improving plants.[6]

Millard W. Sharp, of Vacaville, Calif., in more recent years has produced and introduced several plum varieties. The method he used was to top-work many varieties into a single tree, allow free crossing, plant the seed, and make intensive selection of the resulting seedlings. Of the varieties he introduced, Sharky and Becky Smith have attained commercial importance.

Plum-breeding work has also been undertaken by Albert F. Etter and August Etter at Ettersburg, Calif. In recent years they have used as parents for hybrids Wild Goose, Marianna, Golden Drop, Agen (French prune), Japanese varieties, and Sierra, a peculiar domestica type that grows wild in Trinity County, Calif.; two wild native plums from Mongolia, and the native plums of Kansas. In all, this includes about a dozen species. The outstanding ability to produce new forms shown by the Sierra, the Kansas, and the Trinity plums is of particular interest. The Sierra hybrids exhibit wide variations in tree and fruit characters. These are under test at the present time, but no varieties have been introduced.

Harlan Rockhill, of Conrad, Iowa, has been engaged in fruit breeding since 1895. Among his recent selections are some promising plum hybrids from crosses of Waneta × Apex, Waneta × Moorpark, No. 10 × P. I. 78519, Waneta dwarf seedling × Apex × P. I. 78519. The last-mentioned cross is reported to be particularly hardy in wood and bud, having withstood temperatures of −26° to −36° F. during the winter of 1935–36. This variety and others are being tested further.

Plum Breeding at State and Federal Stations

South Dakota

Work was undertaken at the South Dakota Agricultural Experiment Station in 1895 by Hansen (*15*) in an attempt to select American varieties of plum that would be satisfactory for the Great Plains region. Up to 1937 fully 10,000 native plum seedlings of *Prunus americana* had been grown in an endeavor to find native seedlings better in size and quality than those already grown. Wastesa, Yuteca, Zekanta, Huya, and Topa were selected and named. Yuteca is large; Wastesa is outstanding for size and quality. Hansen attempted to introduce quality into the native plums by crossing these into a number of other species such as peach, cherry, and apricot, as well as with other varieties of plum. The following is a list of crosses made, together with notes on the progeny:

Prunus besseyi Bailey (Bessey cherry or western sand cherry) × apricot plum *P. simonii* Carr. Not hardy, fruits sparingly. One variety only named but the trees have since been discarded.

P. besseyi × Japanese plum (*P. salicina* Lindl.). Progeny highly fertile, hardy. widely cultivated. Among varieties named are Opata, Sapa, and Oka.

P. besseyi × native plum (*P. americana* Marsh.). Two varieties named, Sansoto and Cheresoto, which are highly fertile.

[6] Burbank's achievements and limitations have also been summed up critically by Jones (*22*).

P. besseyi × Apricot (*P. armeniaca* L.). Progeny very shy bearers.

P. besseyi × peach (*P. persica*). Flowers of hybrid (Kamdesa) were sterile.

P. americana × *simonii*. Three varieties named, Toka, Hanska, and Kaga, which are strong pollinators for other varieties. The fruit is fragrant, flesh firm, and of excellent quality.

P. simonii × *americana*. This cross produced Tokata: the fruit is large and of excellent flavor. The seedlings of this cross require cross-pollination.

P. salicina × *americana*. The progeny of this cross is highly fertile. Five varieties have been introduced and widely cultivated—Waneta, Kahinta, Tawena, Oziya, Tecumseh.

P. americana × *salicina*, the reciprocal of the former species cross, has yielded many choice hybrids which are self-fertile and interfertile.

Canada plum (*P. nigra* Ait.) × *P. salicina*. This combination has yielded the varieties Cree and Pembina.

P. salicina × *nigra* has given the variety Ojibwa.

From Canada plum, *Prunus nigra*, pure selections have been made and introduced as Assiniboin and Winnipeg.

Since 1895 selections have been made from over a million seedlings of *Prunus besseyi*. The thirteenth generation has now fruited.

New York

At the New York (State) Agricultural Experiment Station, Geneva, plum breeding was started as early as 1893, when a few open-pollinated seedlings were grown. Under test the seedlings proved to be of no commercial value. From 1908, when the first crosses were made at the New York station, up to the present time, 78 varieties, 6 seedlings, and 7 United States Department of Agriculture introductions have been used in breeding work, and 546 crosses, 16 selfs, and 26 open pollinations have been made. Only 519 seedlings have been planted in the orchard. The set of seed has not been high, and there were serious losses between the time of harvesting the seed and planting. Considerable difficulty has sometimes been experienced in getting the seeds to grow. A few Japanese plums (*Prunus salicina*) have given seedlings, but no seedlings have been obtained from the early-maturing European or domestica group.

It has been the experience in the plum-breeding work at Geneva that it is difficult to obtain large quantities of seed from hand-pollinated trees. The flowering season is usually brief and there is often a high mortality of blossoms. It has been suggested that the use of tents and bees for pollination would be the economical method for securing large numbers. The comparatively few seedlings that have fruited indicate that it is not difficult to make rapid progress in plum improvement. The large-fruited, attractive, poor-quality Grand Duke has given promising new varieties when crossed with high-quality Golden Drop and Agen. Imperial Epineuse and Pearl have also imparted good quality to a high degree in crosses. The varieties that have been used most extensively and the number of times they have been used are: Abundance 23, Agen 23, Albion 8, Archduke 8, Beauty 17, Burbank 57, Clyman 11, Formosa 13, Golden Drop 8, Grand Duke 23, Hall 12, Imperial Epineuse 30, Jefferson 8, Miller Superb 10, Oullins 22, Reine Claude 19, Rivers Early 12, Santa Rosa 16, Shiro 10, Stanley 16, Tragedy 8, and Yellow Egg 28. A list of plum varieties introduced by the New York station is given in table 4.

TABLE 4.—*Plum varieties introduced by the New York (State) Agricultural Experiment Station*

Variety introduced	Parentage	When crossed	Year introduced	Purpose
Albion	Golden Drop × Grand Duke	1908	1929	Very late season.
American Mirabelle	Imperial Epineuse × Mirabelle.	1911	1925	Home and roadside market.
Hall	Golden Drop× Grand Duke	1908	1925	Do.
Stanley	Agen × Grand Duke	1913	1926	Commercial market.

The opinion is expressed by Richard Wellington that by intercrossing hybrids such as Hall, Albion, and Stanley, and by crossing them on high-quality plums such as Imperial Epineuse, varieties of better quality should be obtained. A large number of varieties and species of plums are grown on the grounds of the New York station as basic material for the production of better varieties.

California

The California Agricultural Experiment Station at Davis has grown a large number of varieties of plums on the station grounds. These have been used in studies on pollination and variety behavior under California conditions. Because of the demand for improved varieties of plums, breeding work was started in 1934. Poor germination of plum seeds has been an important factor in slowing down the production of seedlings. All the species of plums grown in North America, together with some miscellaneous species, are being utilized. A complete list is given in the appendix. Genetic and cytological work on interspecific crosses is under way.

Iowa

At the Iowa Agricultural Experiment Station a large number of plum crosses have been made, using *Prunus americana*, *P. salicina*, *P. domestica*, and *P. maritima;* also *P. armeniaca*. Interspecific hybrids between *P. americana* and *P. salicina* are grown, and 180 trees resulting from crosses between species and varieties are now being grown in the nursery at Ames. These crosses were made during the period 1931–33. Varieties used as pollen parents and the number of times they were used are: Elliot 5, Hennepin 4, Japex 2, Monitor 2, Sapa 5, Waneta 6, and Anthony, Zumbra, Red Wing, and Burbank each 1. Crosses between the plum and the Russian and Moorpark apricots have been made. Greenhouse trees are being utilized in the breeding work with *Prunus*, and many hundreds of nonfruiting crosses not listed above have been made on them. The interspecific hybrids that prove to be fertile will be preserved for future crossing. The trees are brought into the greenhouse about January 10 and are ready for crossing about 3 or 4 weeks later.

Minnesota

Plum-breeding work at the Minnesota Agricultural Experiment Station was begun in 1889 at University Farm by S. B. Green, horticulturist. In the same year breeding work was also started by E. H. S.

Dartt at Owatonna Tree Station, a branch station of the University. This work consisted of selection of open-pollinated seed from superior native varieties. More extensive and systematic work began in 1907 with the establishment of the present University of Minnesota Fruit Breeding Farm. Up to the present 20 varieties have been introduced—Anoka, Elliot, Ember, Golden Rod, Hennepin, La Crescent, Mendota, Monitor, Mound, Newport, Nicollet, Radisson, Red Wing, St. Anthony, Superior, Tonka, Underwood, Waconia, Winona, and Zumbra. They are of special interest for the upper Mississippi River Valley area because of their winter hardiness, but are worthy of testing in other sections also, and they should provide material for additional studies. Detailed descriptions of these varieties, their parentage, and the dates of introduction are given in the appendix, which also includes a list of the varieties now being used in further breeding studies.

A considerable amount of breeding material is available involving various species of native and foreign plums and other closely related species of stone fruits. Since winter hardiness is a primary requisite, all breeding material is subjected to severe field tests to determine its resistance to cold.

Federal Field Stations

A number of varieties and specific crosses of plum have been made in cooperative investigations by the Bureau of Plant Industry, United States Department of Agriculture, and Leland Stanford Junior University at Palo Alto, Calif. The following varieties and species have been used as seed parents: Agen, Anita × Sugar, Becky Smith, Burbank, Clyman, Duarte, Fremonti, Giant, Golden Drop, Imperial Epineuse, Improved French, Methley, Pond, Sergeant, Tragedy, Wickson, and *Prunus bokhariensis* Royle. In addition the following varieties have been used as pollen parents: Sugar, Gaviota, Formosa, Santa Rosa, Beauty, Satsuma, Standard, and Tunis. Two promising hybrids, Methley × Wickson and Wickson × Santa Rosa, have been selected. The latter variety is a delicious plum, representing a particularly fine blend of flavors and ripening just after Santa Rosa. The tree is productive and in preliminary tests seems to be well adapted to California conditions. A complete list of plum hybrids produced is given in the appendix to this section.

At the Northern Great Plains Field Station, Mandan, N. Dak., more breeding work has been done with plums than with any other fruit except apples. Thousands of seedlings have been grown from the native wild plum and cultivated varieties. A great deal of variation is to be found within the *Prunus americana* species, and over 50 selections were made, some of which were propagated for a more thorough test. A few of these are ready for more extensive testing in the northern Great Plains area. Of late years a large number of Japanese hybrid seedlings have been grown. Hybridizing work has been in progress, using hardy *P. americana* and *P. nigra* varieties, these being crossed with Japanese varieties, domestica varieties, *P. simonii*, *P. tomentosa* Thunb., apricots, and cherries, and with such hybrid plum varieties as Waneta, Underwood, and Sapa. Some of the progenies are now bearing fruit, and a few selections have been made.

Plum Breeding in Canada
